

An Algebraic Approach to Non-Malleability

Vipul Goyal* Silas Richelson† Alon Rosen‡ Margarita Vald§

Abstract

In their seminal work on non-malleable cryptography, Dolev, Dwork and Naor, showed how to construct a non-malleable commitment with logarithmically-many "rounds"/"slots", the idea being that any adversary may successfully maul in some slots but would fail in at least one. Since then new ideas have been introduced, ultimately resulting in constant-round protocols based on any one-way function. Yet, in spite of this remarkable progress, each of the known constructions of non-malleable commitments leaves something to be desired.

In this paper we propose a new technique that allows us to construct a non-malleable protocol with only a single "slot", and to improve in at least one aspect over each of the previously proposed protocols. Two direct byproducts of our new ideas are a four round non-malleable commitment and a four round non-malleable zero-knowledge argument, the latter matching the round complexity of the best known zero-knowledge argument (without the non-malleability requirement). The protocols are based on the existence of one-way functions and admit very efficient instantiations via standard homomorphic commitments and sigma protocols.

Our analysis relies on algebraic reasoning, and makes use of error correcting codes in order to ensure that committers' tags differ in many coordinates. One way of viewing our construction is as a method for combining many atomic sub-protocols in a way that simultaneously amplifies soundness and non-malleability, thus requiring much weaker guarantees to begin with, and resulting in a protocol which is much trimmer in complexity compared to the existing ones.

Keywords: Non-malleability, commitments, zero-knowledge

1 Introduction

The notion of non-malleability is central in cryptographic protocol design. Its objective is to protect against a man-in-the-middle (MIM) attacker that has the power to intercept messages and transform them in order to harm the security in other instantiations of the protocol. Commitment is often used as the paragon example for non-malleable primitives because of its ability to almost “universally” secure higher-level protocols against MIM attacks.

Commitments allow one party, called the committer, to probabilistically map a message m into a string, $\text{Com}(m; r)$, which can be then sent to another party, called the receiver. In the statistically binding variant, the string $\text{Com}(m; r)$ should be *binding*, in that it cannot be later “opened” into a message $m' \neq m$. It should also be *hiding*, meaning that for any pair of messages, m, m' , the distributions $\text{Com}(m; r)$ and $\text{Com}(m'; r')$ are computationally indistinguishable.

A commitment scheme is said to be *non-malleable* if for every message m , no MIM adversary, intercepting a commitment $\text{Com}(m; r)$ and modifying it at will, is able to efficiently generate a commitment $\text{Com}(\tilde{m}; \tilde{r})$ to a related message \tilde{m} . Interest in non-malleable commitments is motivated both by the central role that they play in securing protocols under composition (see for example [CLOS02, LPV09]) and by the unfortunate reality that many widely used commitment schemes are actually highly malleable. Indeed, man-in-the-middle (MIM) attacks occur quite naturally when multiple concurrent executions of protocols are allowed, and can be quite devastating.

Beyond protocol composition, non-malleable commitments are known to be applicable in secure multi-party computation [KOS03, Wee10, Goy11], authentication [NSS06], as well as a host of other non-malleable primitives (e.g., coin flipping, zero-knowledge, etc.), and even into applications as diverse as position based cryptography [CGMO09].

1.1 Prior Work

Since their conceptualization by Dolev, Dwork and Naor [DDN91], non-malleable commitments have been studied extensively, and with increasing success in terms of characterizing their round-efficiency and the underlying assumptions required. By now, we know how to construct constant-round non-malleable commitments based on any one-way function, and moreover the constructions are fully black-box. While this might give the impression that non-malleable commitments are well understood, each of the currently known constructions leaves something to be desired.

The first construction, due to DDN is perhaps the simplest and most efficient, mainly because it can in principle be instantiated with highly efficient cryptographic “sub-protocols”. This, however, comes at the cost of round-complexity that is logarithmic in the maximum overall number of possible committers. Subsequent works, due to Barak [Bar02], Pass [Pas04], and, Pass and Rosen [PR05] are constant-round, but rely on (highly inefficient) non-black box techniques. Wee [Wee10] (relying on [PW10]) gives a constant-round black-box construction under the assumption that sub-exponentially hard one-way functions exist. This construction employs a generic (and costly) transformation that is designed to handle general “non-synchronizing” MIM adversaries.

Finally, recent works by Goyal [Goy11] and Lin and Pass [LP11] attain non-malleable commitment with constant round-complexity via the minimal assumption that polynomial-time hard to invert one-way functions exist. The Lin-Pass protocol makes highly non-black-box use of the underlying one-way function (though not of the adversary), along with a concept called signature chains;

resulting in significant overhead. Most relevant to the current work is the work of Goyal [Goy11]. Goyal’s protocol, using a later result of Goyal, Lee, Ostrovsky and Visconti [GLOV12], can be made fully black-box, with its only shortcomings being high-communication complexity and the use of the Wee transformation (or alternatively a similarly costly transformation due to Goyal [Goy11]) for handling non-synchronizing adversaries. To construct non-malleable commitments, our work follows the blueprint proposed by Goyal, and introduces new proof techniques to significantly trim down its complexity, making various parts of the protocol of Goyal [Goy11] unnecessary.

The current state of affairs is such that in spite of all the remarkable advances, the DDN construction and its analysis remain the simplest and arguably most appealing candidate for non-malleable commitments. This is both due to its black-boxness and because it does not require transformations for handling a non-synchronizing MIM (in fact, the protocol is purposefully designed to introduce asynchronicity in message scheduling, which can be then exploited in the analysis).

1.2 Our Results

In this work we introduce a new algebraic technique for obtaining non-malleability, resulting in a simple and elegant non-malleable commitment scheme. The scheme’s analysis contains many fundamentally new ideas allowing us to overcome substantial obstacles without sacrificing efficiency. The protocol is constructed using any statistically binding commitment scheme as a building block, and hence requires the minimal assumption that one way functions exist.

Theorem. *Assume the existence of one-way functions. Then there is a 4-round non-malleable commitment scheme.*

Our protocol enjoys the following appealing features, each of which makes it preferable in at least one way over any of the previously proposed protocols for non malleable commitment:

Simplicity. Compared to all previous protocols, ours is significantly simpler to describe and to instantiate (though not to analyze). The simplicity of the protocol also means that there is no need to introduce costly transformations for handling non-synchronizing adversaries.

Efficiency. In particular, ours is significantly more efficient than all prior protocols both in terms of round complexity, and in the sense that we use a surprisingly small number of sub-protocols, each of which can be instantiated in a very efficient way (e.g. using standard sigma protocols).

Assumption. The assumption underlying our main protocol is the existence of one-way functions, which is necessary for non-malleable commitments.

A direct consequence of our protocol is a 4-round non-malleable zero-knowledge argument based on any OWF. This demonstrates that for zero-knowledge, non-malleability does not necessarily come at the cost of extra rounds of interaction or complexity assumptions.

Theorem. *Assume the existence of one-way functions. Then there is a 4-round black-box non-malleable zero-knowledge argument for every language in NP.*

Beyond the above virtues, we believe that our new techniques are actually the most significant contributions of this work. In addition to our use of algebra, we make novel combinatorial use of error correcting codes in order to ensure that different committers’ tags differ in many coordinates (more on that later on). Whereas prior work relied on “worst-case” analysis of differences in committers’ tags, ours follows from an “average-case” claim.

One way of viewing our construction is as a method for combining n atomic sub-protocols in a way that simultaneously amplifies their soundness and non-malleability properties, thus requiring much weaker soundness and non-malleability to begin with. We hope that this paradigm will become the norm for future work on in the area as, despite requiring more careful and strenuous analysis, it leads to pleasantly lightweight protocols. For example, this technique alone allows for an immediate linear reduction in communication complexity compared with its nearest relative, Goyal’s protocol.

Another payoff of the algebraic techniques we employ is that our protocol only has one “slot”. Nearly all of the non-malleable commitment schemes in the literature use multiple slots of interaction as a way to set up imbalances between the two different protocol instantiations that the MIM is involved in. The well known “two slot trick” of [Pas04, PR05, Goy11], for example, is a way to turn an arbitrary asymmetry between the instantiations into two: one which is heavy on the right and one on the left. The inability of the MIM to align the imbalances is crucial to the proof of non-malleability. Running the two slots in parallel introduces several technical problems, most notably “if the two imbalances are side by side, won’t they just cancel each other out?” Our analysis uses a computational version of the “linear independence of polynomial evaluation” mantra in order to argue that the MIM cannot combine the two imbalances and must deal with each one separately.

We stress that the use of algebra and error correcting codes does not yield such reward for free: the analysis required becomes substantially more difficult. In the next section we describe and briefly discuss our new protocol and extractor. We then outline our techniques, keeping it informal but pointing out several of the challenges faced and new ideas required to overcome them.

1.3 The New Protocol

Suppose that committer C wishes to commit to message m , and let $t_1, \dots, t_n \in \mathbb{Z}$ be a sequence of tags that uniquely correspond to C ’s identity (more on the tags later). Let Com be a statistically binding commitment scheme, and suppose that $m \in \mathbb{F}_q$ where $q > \max_i 2^{t_i}$. The protocol proceeds as follows:

1. C chooses random $\mathbf{r} = (r_1, \dots, r_n) \in \mathbb{F}_q^n$ and sends $\text{Com}(m)$ and $\{\text{Com}(r_i)\}_{i=1}^n$ to R ;
2. R sends C a query vector $\boldsymbol{\alpha} = (\alpha_1, \dots, \alpha_n)$ where each α_i is drawn randomly from $[2^{t_i}] \subset \mathbb{F}_q$;
3. C sends R the response $\mathbf{a} = (a_1, \dots, a_n)$ where $a_i = r_i \alpha_i + m$;
4. C proves in ZK that the values \mathbf{a} (from step 3) are consistent with m and \mathbf{r} (from step 1).

The statistical binding property of the protocol follows directly from the binding of Com . The hiding property follows from the hiding of Com , the zero-knowledge property of the protocol used in step 4, and from the fact that for every i the receiver R observes only a single pair of the form (α_i, a_i) , where $a_i = r_i \alpha_i + m$.

Note the role of C ’s tags in the protocol: t_i determines the size of the i –th coordinate’s challenge space. Historically, non-malleable commitment schemes have used the tags as a way for the committer to encode its identity into the protocol as a mechanism to prevent M (whose tag is different from C ’s tag) from mauling. In our protocol the tags play the same role, albeit rather passively. For example, though the size of the i –th challenge space depends on t_i , the size of the total challenge space depends only on the sum $\sum_{i=1}^n t_i$ of the tags. In particular, our scheme leaves open the possibility that the left and right challenge spaces might have the same size (in fact this

will be ensured by our choice of tags). This raises a red flag, as previous works go to great lengths to set up imbalances between the left and right challenge spaces in order to force M to “give more information than it gets”. Nevertheless, we are able to prove that any mauling attack will fail.

At a very high level, our protocol can be seen as an algebraic abstraction of Goyal’s protocol. However, the fundamental difference we should emphasize from [Goy11] is that he crucially relies on the challenge space in the left interaction being much smaller than the challenge space in the right. For us, the challenge spaces in the two interactions are exactly the same size and so the techniques of [Goy11] do not apply to our setting—at least at first. Our protocol does have small imbalances between the challenge spaces of individual coordinates, which is what we will eventually use to prove non-malleability. However, proving that the coordinates are sufficiently independent so that these imbalances accrue to something usable is completely new to this work.

1.4 Proving Non-Malleability

Consider a MIM adversary M that is playing the role of the receiver in a protocol using tags t_1, \dots, t_n while playing the role of the committer in a protocol using tags $\tilde{t}_1, \dots, \tilde{t}_n$ (we describe explicitly how to construct the tags from C ’s identity in Section 2). We refer to the former as the “left” interaction and to the latter as the “right” interaction. We let m and \tilde{m} denote the messages committed to in the left and right interactions respectively. One nice feature of our protocol is that it is automatically secure against a non-synchronizing adversary, simply because there are so few rounds, there is no way for the MIM to benefit by changing the message order: any scheduling but the synchronous one can be dealt with trivially. So the only scheduling our proof actually needs to handle is a synchronizing one, as depicted in Figure 1 below.

Figure 1: Protocol with Man-in-the-Middle

Our proof of non-malleability involves demonstrating the existence of an extractor, E , who is able to rewind M and extract \tilde{m} without needing to rewind C in the left instantiation. Our extractor is modeled after Goyal’s extractor which: (1) rewinds M to where $\tilde{\boldsymbol{\alpha}}$ was sent and asks a new query $\tilde{\boldsymbol{\beta}}$ instead, and (2) responds to M ’s left query randomly (it cannot do better without rewinding C as it does not know m), hoping that M answers correctly on the right.

In Goyal’s protocol there is no way for E to know whether M answered correctly or not, and so it must have a verification message after the query response phase so E can compare M ’s answer with

the main thread to verify correctness. We sidestep this necessity in the following way. We rewind to the beginning of step 2 twice and ask two new query vectors $\tilde{\beta}$ and $\tilde{\gamma}$, we answer randomly on the left obtaining $\{(\tilde{\alpha}, \tilde{\mathbf{a}}), (\tilde{\beta}, \tilde{\mathbf{b}}), (\tilde{\gamma}, \tilde{\mathbf{c}})\}$, where $(\tilde{\alpha}, \tilde{\mathbf{a}})$ is from the main thread. Comparing both $(\tilde{\beta}_i, b_i)$ and $(\tilde{\gamma}_i, c_i)$ with $(\tilde{\alpha}_i, a_i)$ will result in candidate values \tilde{m}_i and \tilde{m}'_i , but with no verification message it is not clear how E should verify which one (if either) is correct. We accomplish this with the following “collinearity test”. If $\tilde{m}_i = \tilde{m}'_i$ then E checks whether the points $\{(\tilde{\alpha}_i, \tilde{a}_i), (\tilde{\beta}_i, \tilde{b}_i), (\tilde{\gamma}_i, \tilde{c}_i)\}$ are collinear. If so, E deems that \tilde{m}_i was the correct value. This requires proving that M cannot answer “incorrectly but collinearly”.

Tags in Error Corrected Form. This discussion is meant for readers who are familiar with the roles of tags in previous non-malleable commitment schemes, for a more thorough introduction see Section 2. Just as in many of the existing NMC schemes, our protocol consists of n “atomic subprotocols”, one for each tag. Previous schemes use the so called “DDN trick” [DDN91] in order to turn C’s k -bit identity into a list of n ($= k$) tags t_1, \dots, t_n , satisfying the properties: (1) each t_i is of length $\log n + 1$; and (2) if $\{t_i\}_i$ and $\{\tilde{t}_j\}_j$ are the tags resulting from two distinct identities then there exists some i such that t_i is completely distinct from $\{\tilde{t}_j\}_j$, meaning that $t_i \neq \tilde{t}_j$ for all j .

Previous schemes’ security proofs require the extractor to be able to use any completely distinct left subprotocol (i.e., one whose tag is completely distinct from $\{\tilde{t}_j\}_j$) to extract M’s commitment \tilde{m} with high probability. This ensures that extraction is possible even in the worst case when there is a single such subprotocol. It also introduces a good deal of redundancy into the protocol.

While one would generally expect most pairs of distinct identities to result in pairs of tags such that property (2) holds for many i , all the DDN trick can guarantee in the worst case is that it holds for a single i (since M is allowed to choose his identity adversarially, this worst case situation might very well be realized). If however, one first applies an error correcting code to C’s identity obtaining, say, a codeword in \mathbb{F}^n for suitably chosen finite field \mathbb{F} with $|\mathbb{F}| = \text{poly}(n)$, then applying the DDN trick to this codeword would yield tags such that (1) t_i is of length $\mathcal{O}(\log n)$; and (2) t_i is completely distinct from $\{\tilde{t}_j\}_j$ for a constant fraction of the $i \in \{1, \dots, n\}$.

Our “completely distinct on average” property requires only that extraction is possible from a completely distinct left subprotocol with constant probability, since there now are guaranteed to be many extraction opportunities. This allows us to remove much of the artificial redundancy resulting in an incredibly trim protocol.

Non-malleability against a copying M. To get a sense of why we might expect our scheme to be non-malleable, let us examine the situation against an M who attempts to maul C’s commitment by simply copying its messages from the left interaction to the right. Let m be the message committed to on the left and let $\{t_i\}_{i=1}^n$ and $\{\tilde{t}_i\}_{i=1}^n$ be the corresponding tags.

After the first message, M will have copied C’s commitments over to the right interaction, successfully committing to the coefficients of the linear polynomials $\tilde{f}_i(x) = r_i x + m$, $i = 1, \dots, n$. The hiding of Com ensures it does not know the polynomials themselves, and so when it receives the right query vector $\tilde{\alpha}$, its only hope of coming up with the correct valuations $\tilde{f}_i(\tilde{\alpha}_i)$ is to copy R’s challenge to the left interaction and copy C’s response back. However, it is unlikely that this will be possible. Indeed, M can only copy $\tilde{\alpha}_i$ over to the left when $\tilde{\alpha}_i \in [2^{t_i}]$. If $\tilde{t}_i > t_i$ then the i -th challenge space on the right is at least twice as big as the i -th challenge space on the left, which means that the probability $\tilde{\alpha}_i$ can be copied is at most $1/2$. We will use a code which ensures that

$\tilde{t}_i > t_i$ for a constant fraction of the i , making the probability that M can copy every coordinate of R 's query vector $\tilde{\alpha}$ negligible. So M will not be able to successfully answer R 's query and complete the proof when performing the “copying” attack.

Non-malleability against general M . Establishing security against a general man-in-the-middle adversary is significantly more challenging, and this is where the bulk of the new ideas are required. Our proof of non-malleability will require us to delve into the full range of possibilities for M 's behavior. In each case, we will show that one of three things happen:

1. M does not correctly answer its queries with good enough probability;
2. E succeeds in extracting \tilde{m} with sufficient probability;
3. an M with such behavior can be used to break the hiding of Com .

The core of our result can be seen as a reduction from a PPT M who correctly answers its queries with non-negligible probability and yet causes E to fail, to a machine \mathcal{A} who breaks the hiding of Com . The following is a very high level outline of our proof.

We define **USEFUL** to be the set of transcripts which do not lead to situation 1 above; that is, transcripts for which M has a good chance of completing the protocol given the prefix. This is important in order for E to have any chance of successfully extracting \tilde{m} . Indeed, if M just aborts in every rewind, E will have no chance. From this standpoint, **USEFUL** is the set of transcripts which give E “something to work with.” We prove that most transcripts are in **USEFUL** in Claim 3.

We then define **EXT**, the set of “extractable” transcripts, on which E will succeed with high probability. These are the transcripts which lead to situation 2. Intuitively, **EXT** is the set of transcripts such that M has good probability of correctly answering a query in a rewind despite the fact that E provides random answers to M 's queries. We prove that indeed, if a transcript is in **EXT** then E succeeds in extracting \tilde{m} .

Finally, we define **TRB**, the set of “troublesome” transcripts which are both useful and not extractable. Transcripts in **TRB** are problematic as on the one hand, usefulness ensures that the prefix is such that if M receives correct responses to its queries on the left, it gives correct responses to the queries on the right. At the same time however, transcripts in **TRB** are not extractable and so the prefix is also such that if M receives random responses to its queries on the left it answers the right queries incorrectly. Certainly, the hiding of Com ensures that M cannot *know* whether it receives correct or random responses to its queries on the left. So this difference in behavior suggests that we may be able to use M to violate the hiding of Com , leading to situation 3 above.

Our main claim in this part of our proof is Claim 8, which says that if the left challenge α has a superpolynomial number of preimage right challenges $\tilde{\alpha}$ then either E succeeds in extracting \tilde{m} , or M can be used to break hiding. Such a claim has been at core of the analysis of some previous NMC schemes. In fact, as many previous schemes (such as [Goy11], for example) use multiple slots in order to *ensure* that some slot has a right challenge space that is much bigger than the left, such a claim often encompasses nearly the entire analysis. In our case, we have some work still left as there is only a single slot and the right and left challenge spaces have the same size. Nevertheless, we are able to prove, using a series of combinatorial arguments, that any mauling attack will wind up with M 's left query having exponentially many preimage right queries.

To see these techniques in action, define the set $S = \{i \in [n] : \tilde{t}_i \leq t_i\}$, and consider an M who simply copies the right challenges $\tilde{\alpha}_i$ for $i \in S$ over to the left but who makes sure to produce a legal query in the coordinates not in S on the left. As $[2^{\tilde{t}_i}] \subset [2^{t_i}]$ for all $i \in S$, copying $\tilde{\alpha}_i$ when $i \in S$ is fine. If we think of M as a map sending right challenge $\tilde{\alpha}$ to left challenge α , then for any $\tilde{\alpha}_S = (\tilde{\alpha}_i)_{i \in S}$, M sends $\tilde{\alpha}'$ such that $\tilde{\alpha}'_S = \tilde{\alpha}_S$ to α' such that $\alpha'_S = \tilde{\alpha}_S$. In other words, M maps the set of right query vectors whose S -coordinates are fixed to $\tilde{\alpha}_S$ to the set of left query vectors whose S -coordinates are also fixed to $\tilde{\alpha}_S$. However, the sizes of these subsets of right and left challenges are

$$\prod_{i \notin S} 2^{\tilde{t}_i} \text{ and } \prod_{i \notin S} 2^{t_i},$$

respectively, and $\prod_{i \notin S} 2^{\tilde{t}_i} = 2^{\Omega(n)} \prod_{i \notin S} 2^{t_i}$ (we are using that our tags are in error-corrected form, which ensures $|[n] \setminus S| = \Omega(n)$). So we see that M , when restricted to the right challenges with S -coordinates fixed to $\tilde{\alpha}_S$, is exponentially many to one on average, and so α has exponentially many preimages with high probability.

4-Round Non-Malleability. The protocol in Figure 1 is explained sequentially, and as written, consists of 8 rounds: two for Naor’s commitment, two for the query/response phase, and four for the ZK argument. However, it can be parallelized down to four rounds using the Feige-Shamir four round ZK argument system [FS90]. This requires running the entire ZK argument in parallel with the commit, query and response messages. We make use of the fact that the statement to be proven can be chosen during the last round of the protocol, and that Feige-Shamir is actually an argument of knowledge, both of which have been used often in the literature. Armed with a 4-round NMC scheme, 4-round ZK is obtained essentially by running a 4-round ZK argument protocol (we again use Feige-Shamir) in parallel with a non-malleable commitment to the witness w .

Many-Many Non-Malleability. Many-many or concurrent non-malleability considers a setting where the MIM can run polynomially many protocols on the left and right (interleaved arbitrarily). It can be demonstrated to hold for our protocol using known techniques. First, one can show that our protocol is one-many non-malleable following [Goy11]. The key point is that the extractor we construct during our proof of non-malleability is able to extract \tilde{m} from the right interaction with high probability, without rewinding the left execution. Therefore, by the union bound, our extractor will succeed in extracting from all of the right interactions with high probability. Next, we use the transformation of [LPV08], that one-many non-malleability implies many-many non-malleability. Their proof uses a hybrid argument to say that one-many non-malleability ensures that non-malleability is retained when adding polynomially many left executions, one by one.

Using the OWF in a Blackbox Fashion. The protocol described in Figure 1 makes non-blackbox use of the OWF during the ZK part of the protocol. It is often desirable for protocols to make only blackbox use of their building blocks, as the alternative tends to be vastly less efficient. To this end, the work of [GLOV12] replaces the ZK proof in the [Goy11] NMC scheme with an “MPC in the head” computation [IKOS07], resulting in a constant round NMC scheme which makes blackbox use of a OWF. The same transformation works for our protocol as well. We point out, however, that all the ZK argument in our protocol has to do is prove “knowledge of committed values” and that these values satisfy a linear equation, both of which can be proved very efficiently (*i.e.*, without resorting to costly \mathcal{NP} -reductions), assuming DDH (or other widely used hardness assumptions). Therefore, if a statistically binding commitment scheme is available that has an

efficient proof of knowledge of committed value, our protocol will be much more efficient than the generic transformation of [GLOV12], which requires C to imagine an entire MPC in his head.

It is worth noting that directly plugging in the ideas of [GLOV12] into our protocol results in a 6-round NMC scheme. We do not address the issue of trying to reduce the round complexity of this blackbox protocol to 4 because our 4-round non-blackbox protocol is so much faster in practice.

2 Preliminaries

For positive $n \in \mathbb{N}$, let $[n] = \{1, \dots, n\}$. A function $\varepsilon : \mathbb{N} \rightarrow \mathbb{R}^+$ is *negligible* if it tends to 0 faster than any inverse polynomial *i.e.*, for all constants c there exists $n_c \in \mathbb{N}$ such that for every $n > n_c$ it holds that $\varepsilon(n) < n^{-c}$. We use $\mathbf{negl}(\cdot)$ to specify a generic negligible function. We abbreviate “probabilistic polynomial time” with PPT. We assume familiarity with computational indistinguishability and zero-knowledge proofs (and related protocols).

2.1 Commitment schemes

Commitment schemes are protocols which enable a party, known as the committer C, to commit himself to a value while keeping it secret from the (potentially cheating) receiver, R. This property is known as hiding. Additionally, upon receiving the commitment from C, R is ensured that even if C cheated, there is at most one value that C can decommit to during a later, decommitment phase (binding). In this work, we consider commitment schemes that are statistically-binding which means that the hiding property only holds against computationally bounded adversaries.

Definition 1 (Statistically Binding Commitment Scheme). *Let $\langle C, R \rangle$ be an interactive protocol between C and R. We say that $\langle C, R \rangle$ is a statistically binding commitment scheme if the following properties hold:*

Correctness: If C and R do not deviate from the protocol, then R should accept (with probability 1) during the decommit phase.

Binding: For every C^* , there exists a negligible function $\mathbf{negl}(\cdot)$ such that C^* succeeds in the following game with probability at most $\mathbf{negl}(\lambda)$: On security parameter 1^λ : C^* first interacts with R in the commit phase to produce commitment c . Then C^* outputs two decommitments (c, m_0, d_0) and (c, m_1, d_1) , and succeeds if $m_0 \neq m_1$ and R accepts both decommitments.

Hiding: For every PPT receiver R^* and every two messages m_0, m_1 , the view of R^* after participating in the commitment phase, where C committed to m_0 is indistinguishable from its view after participating in a commitment to m_1 .

[Nao91] gives a 2-round, statistically binding bit commitment scheme that can be built from any OWF [HILL99].

2.2 Non-malleable commitments

We wish for our commitment scheme to be impervious to a MIM adversary, M, who takes part in two protocol executions (in the left interaction M acts as the receiver while in the right, M plays the role of the committer), and tries to use the left interaction to affect the right. The security property we desire can be summarized:

For any MIM adversary M , there exists a standalone machine who plays only one execution as the committer, yet whose commitment is indistinguishable from M 's commitment on the right.

At first glance, non-malleability seems impossible as surely nothing can be done to protect against a MIM who simply copies messages from one protocol execution to another. For this reason, non-malleable security offers protection only against any MIM who tries to change messages in a meaningful way.

On the Existence of Identities. In this work, just as in [DDN91, PR05], we assume that the committer has an identity $id \in \{0, 1\}^k$. In order to perform a successful mauling attack, a MIM has to maul a commitment corresponding to C 's identity into a commitment of his own, distinct identity. Though this sounds like a strong assumption on the network, essentially requiring that “you know who you are talking to”, for our purposes, it is actually equivalent to the requirement discussed above, that the MIM do something other than simply copy messages. This is because our protocol is interactive, and the first committer message contains a statistically binding commitment to m . This means that if we set the committer's identity to be the first committer message, C 's and M 's identities will be distinct unless M copied C 's first message.

Moving forward, we assume that the committer's id is externally given and we require that non-malleability holds only in the case when C and M 's identities are different. We also assume for simplicity that player identities are known before the protocol begins, though strictly speaking this is not necessary, as the identities do not appear in the protocol until after the first committer message. We point out that M can choose his identity adversarially, as long as it is not equal to C 's.

Definition of Non-Malleable Commitments. In this work, we consider the notion of non-malleability with respect to commitment and we will frequently refer to the “message committed to by a MIM adversary M during the commitment phase”. We note that this is uniquely defined, as all commitment schemes in this work are statistically binding, and so for all but a negligible fraction of the possible transcripts \mathbb{T} of the interaction between M and an honest receiver R , there exists at most one message m that is consistent with \mathbb{T} (*i.e.*, for which there exist random coin tosses which give \mathbb{T}). We recall the definition of non-malleable commitments of Lin et al *et al.* [LPV08].

The man-in-the-middle execution. In the man-in-the-middle execution, the MIM adversary M is simultaneously participating in two interactions called the left and the right interaction. In the left interaction M is the receiver and interacts with a honest committer whereas in the right interaction M is the committer and interacts with a honest receiver. We define a random variable $\mathbf{MIM}_{(C,R)}(m, z)$ describing (\tilde{m}, v) : the value M commits to in the right interaction, and M 's view in the full experiment. Specifically, M has auxiliary information z and interacts on the left with an honest committer C with input message m and identity id and on the right with honest receiver R . M attempts to commit to a value \tilde{m} that is related to m using an identity \tilde{id} of its choice. If the right commitment (as determined by the transcript) is invalid or undefined, or $id = \tilde{id}$ its value is set to \perp .

The simulated execution. In the simulated execution a simulator \mathcal{S} interacts with an honest receiver R . \mathcal{S} receives security parameter 1^λ and auxiliary information z and interacts with the honest receiver R . Let $\mathbf{SIM}_{(C,R)}^{\mathcal{S}}(1^\lambda, z)$ denote the random variable describing (\tilde{m}, v) : the value \mathcal{S}

commits to in the right interaction, and \mathcal{S} 's view during the entire experiment. If the commitment produced by \mathcal{S} is invalid or undefined, its value is set to \perp .

Definition 2 (Non-Malleable Commitments). *A commitment scheme $\langle C, R \rangle$ is non-malleable with respect to commitment if for every PPT MIM adversary M , there exists a PPT simulator \mathcal{S} such that the following ensembles are indistinguishable:*

$$\{\text{MIM}_{\langle C, R \rangle}(m, z)\}_{m \in \{0,1\}^\lambda, z \in \{0,1\}^*}, \text{ and } \{\text{SIM}_{\langle C, R \rangle}^{\mathcal{S}}(1^\lambda, z)\}_{z \in \{0,1\}^*, id \in \{0,1\}^k}$$

2.3 Tags in Error Corrected Form

In this section, we describe how to derive the tags from C 's identity, highlighting the properties we will use moving forward. Let $id \in \{0,1\}^k$ be C 's identity and let $\mathbf{y} \in \mathbb{F}^{n/2}$ be the image of id under an error correcting code with constant distance, for a suitable finite field \mathbb{F} . Constant distance implies that if $id, \tilde{id} \in \{0,1\}^k$ are distinct identities then \mathbf{y} and $\tilde{\mathbf{y}}$ differ on a constant fraction of their coordinates. Now, set

$$t_i = \begin{cases} 2i|\mathbb{F}| + y_i, & i \leq n/2 \\ (2n+1)|\mathbb{F}| - t_{n-i+1}, & i > n/2 \end{cases}$$

Note that $2i|\mathbb{F}| \leq t_i < (2i+1)|\mathbb{F}|$ for all i . The following is a list of useful properties that the tags satisfy. Let $\{t_i\}_i$ and $\{\tilde{t}_i\}_i$ be the tags resulting from distinct identities $id \neq \tilde{id}$.

1. **Ordered:** $t_1 < t_2 < \dots < t_n$;
2. **Well Spaced:** $t_1 = \omega(\log \lambda)$ and $t_{i+1} - t_i = \omega(\log \lambda)$ for all $i \in [n]$; moreover $t_{i+1} - \tilde{t}_i = \omega(\log \lambda)$.
3. **Good Distance and Balance:** if $i \neq j$ then $t_i \neq \tilde{t}_j$; moreover $t_i < \tilde{t}_i$ holds for a constant fraction of $i \in [n]$ (as does $t_i > \tilde{t}_i$).

Properties 1 and 2 follow immediately as long as $|\mathbb{F}| = \omega(\log \lambda)$. Property 3 follows from 1) the distance of the error correcting code as $t_i = \tilde{t}_i$ iff $y_i = \tilde{y}_i$ which must not be the case for a constant fraction of the $i \in [n]$; along with 2) if $t_i \neq \tilde{t}_i$ then either $t_i < \tilde{t}_i$ or else $t_{n-i} < \tilde{t}_{n-i}$. This is reminiscent of the two slot trick of [Pas04, PR05].

It remains to select parameters. Note that we have already touched on the role that the tags play in our protocol: the size of the challenge space in coordinate i is 2^{t_i} . This means that we would like to make the tags as small as possible, while still allowing our security proof to go through. We make the conservative selection $n = \mathcal{O}(\lambda)$ and $|\mathbb{F}| = \log^2(\lambda)$ to ensure both that the above properties hold and that all that is required of the error correcting code is that it has constant distance and constant rate. Codes with such properties are known to exist. We could use, for example polynomial based codes such as Reed-Muller codes, the multivariate generalization of Reed-Solomon codes. This results in the overall communication complexity of our non-malleable commitment scheme being $\tilde{\mathcal{O}}(\lambda^2)$. Slightly better communication complexity might be available through more aggressive choices of parameters or better codes. We do not press the issue further.

3 The Protocol

In this section, we describe our protocol given tags t_1, \dots, t_n in error corrected form as described in Section 2.3. We use Naor's two round, statistically binding bit commitment scheme [Nao91] as a

building block.¹ We use boldface to denote vectors; in particular a challenge vector $\alpha = (\alpha_1, \dots, \alpha_n)$ and a response vector $\mathbf{a} = (a_1, \dots, a_n)$. We write **Com** for the entire first commitment message, so $\mathbf{Com} = (\text{Com}(m), \text{Com}(r_1), \dots, \text{Com}(r_n))$. Our non-malleable commitment scheme $\langle C, R \rangle$ between a committer C trying to commit to m and a receiver R appears in Figure 2. The decommitment phase is done by having the committer C send m and the randomness it used during the protocol.

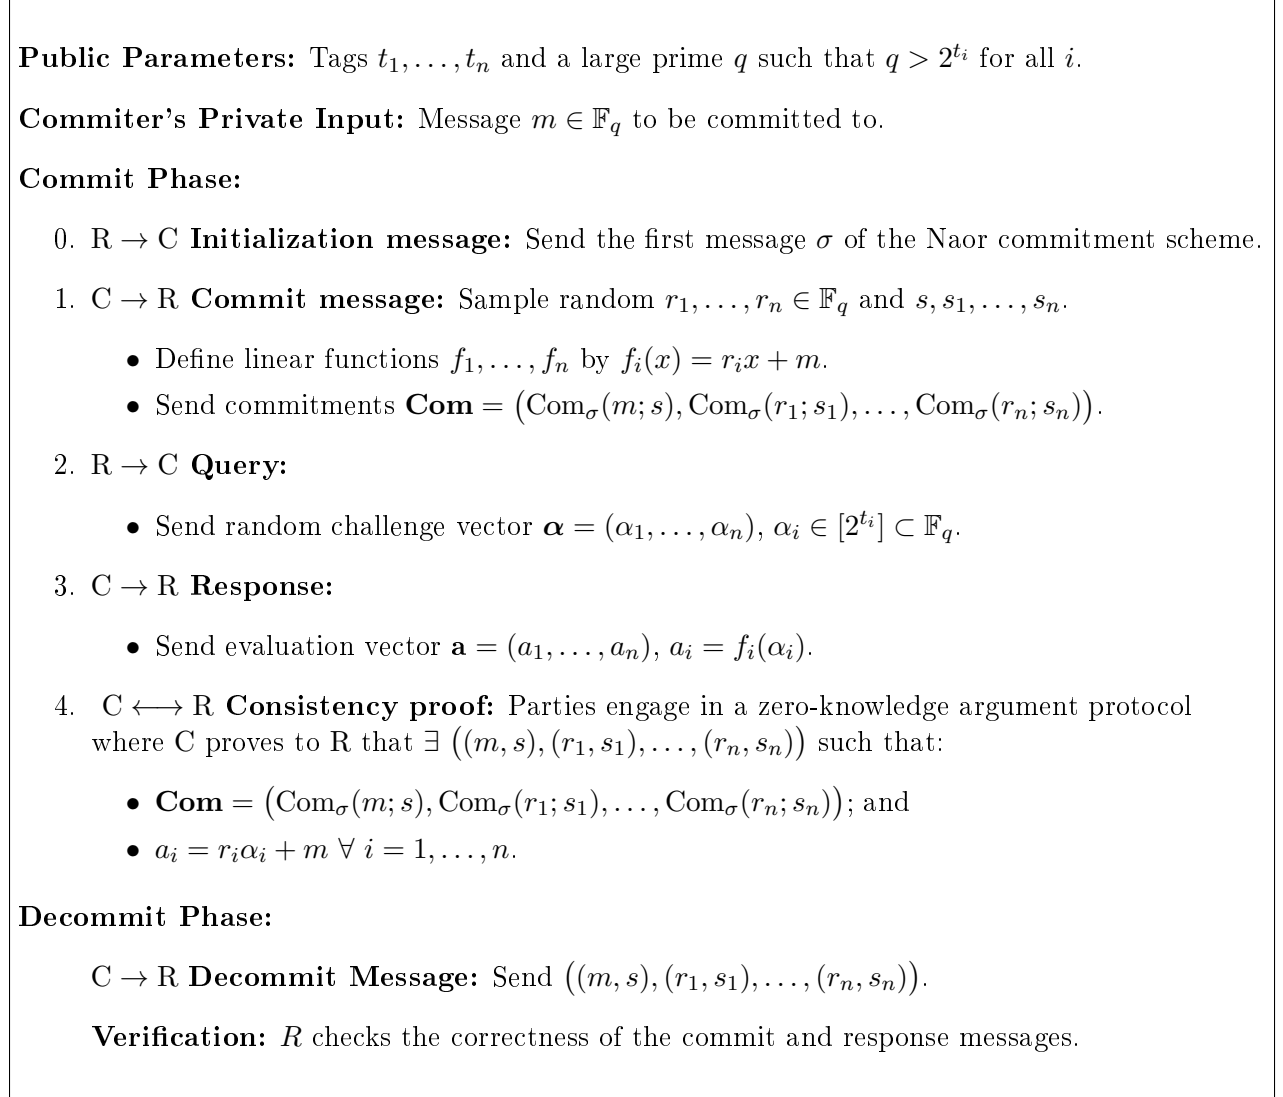

Figure 2: The non-malleable commitment scheme $\langle C, R \rangle$.

Proposition 1. *The commitment scheme $\langle C, R \rangle$ is computationally hiding and statistically binding.*

¹Briefly recall Naor's scheme: 1) R sends random initialization message σ , and 2) C responds with $\text{Com}_\sigma(m; s)$, a commitment to $m \in \{0, 1\}$ using randomness s (we will feel free to just write $\text{Com}(m)$, surpressing σ and s for simplicity). We comment that the same initialization message σ can be used for polynomially many parallel instantiations of the scheme, allowing C to commit to $m \in \mathbb{Z}_q$ one bit at a time (actually [Nao91] shows how to commit to longer messages more efficiently).

Proof Sketch. Statistical binding follows from the statistical binding property of the underlying commitment scheme Com . To prove computational hiding, we consider the following hybrid experiments.

1. Simulate the ZK consistency proof step. Indistinguishability follows from the ZK property.
2. For each $i \in [n]$, replace the commitment $\text{Com}(r_i)$ to be a commitment to random value. Indistinguishability follows from the hiding of Com .
3. Replace the polynomials with random polynomials $\bar{f}_1, \dots, \bar{f}_n$ such that $\bar{f}_i(\alpha_i) = f_i(\alpha_i)$ and $\bar{f}_i(0) = m'$ for randomly sampled m' and all $i \in [n]$. The indistinguishability follows from having $n + 1$ variables and only n equations.
4. Change the commitment $\text{Com}(m)$ to be a commitment to a random string (as opposed to a commitment to m). Indistinguishability follows from the hiding of Com .

In the final hybrid, the transcript of the commitment stage contains no information about the value m being committed to, and so no information about m is leaked by the protocol. \square

Theorem 1 (Main theorem). *The commitment scheme $\langle C, R \rangle$ is non-malleable against a synchronizing adversary.*

We comment that non-malleability against a general *non-synchronizing* adversary actually holds in the above protocol (provided we choose a ZK with suitable properties, such as [FS90]). However, we only prove non-malleability against a synchronizing MIM (*i.e.*, one who plays corresponding messages of the two instantiations one after the other) because the large number of messages of the protocol above make it cumbersome to examine all possibilities for M's scheduling.

We defer the proof of non-malleability against non-synchronizing M until after we parallelize our protocol down to four rounds (see Section 6). This makes it much easier (in fact trivial) to directly examine all of the non-synchronizing options for message scheduling that M has available.

4 Proof of Non-Malleability

In this section we prove Theorem 1. Recall from Definition 2 that we must show that for any PPT MIM M there exists a PPT simulator \mathcal{S} such that

$$\{\mathbf{MIM}_{\langle C, R \rangle}(m, z)\}_{m, z} \approx_c \{\mathbf{SIM}_{\langle C, R \rangle}^{\mathcal{S}}(1^\lambda, z)\}_{z, id},$$

where the distributions output (\tilde{m}, v) : the commitment in the right interaction and view after the commit phases of both executions are complete in the real and ideal worlds, respectively. Our simulator is a very simple machine who runs M internally, committing honestly to $0 \in \mathbb{Z}_q$ on the left and forwarding M's messages on the right to an honest receiver R.

We prove indistinguishability of the above distributions for any M by constructing an extractor E which takes M's view after the commit phases of the left and right executions are complete and outputs its commitment \tilde{m} in the right execution whp. It follows that an algorithm which distinguishes $\mathcal{D}_0 = \{\mathbf{MIM}_{\langle C, R \rangle}(m, z)\}_{m, z}$ from $\mathcal{D}_1 = \{\mathbf{SIM}_{\langle C, R \rangle}^{\mathcal{S}}(1^\lambda, z)\}_{z, id}$ can be used to break the hiding of $\langle C, R \rangle$ in the following way: 1) let v be M's view after completing the commit phases of the left and right executions in either the real or ideal world; 2) use E to obtain the pair (\tilde{m}, v) ;

3) use the distinguisher to determine whether M’s interaction took place in the real or ideal world. This breaks the hiding of the left commitment as the only difference between the worlds is that in the real, C commits to m while in the ideal, \mathcal{S} commits to 0.

Formally, we assume that there exists a PPT distinguisher D such that

$$\left| \Pr_{(\tilde{m}, v) \leftarrow \mathcal{D}_0} (D(\tilde{m}, v) = 1) - \Pr_{(\tilde{m}, v) \leftarrow \mathcal{D}_1} (D(\tilde{m}, v) = 1) \right| \geq 2p$$

for some non-negligible $p = p(\lambda)$. We prove that E succeeds with probability at least $1 - p$. Note this suffices for proving non-malleability since it means that E extracts \tilde{m} AND the D will use (\tilde{m}, v) to determine whether M is interacting with C committing to m , or \mathcal{S} committing to 0. We also assume without loss of generality that M is deterministic and that M’s probability of successfully completing the protocol (over C’s and R’s random coins) is at least p .

4.1 The Extractor E

The high level description of our extractor (described formally in Figure 3) is quite simple. Intuitively, our protocol begins by C committing to n , threshold 2, Shamir secret sharings [Sha79] of m ; R then asks for one random share from each sharing, which C gives. All E does is rewind M to the beginning of the right session’s query phase ask for a new random share. Since E gets one share as part of its input, this will allow E to reconstruct \tilde{m} .

The problem with this approach is that E does not know the value C has committed to on the left and so it does not know how to answer M’s query on the left correctly. The best E can do is give a random response on the left and hope that M will give a correct response on the right anyway. On the one hand, the hiding of Com dictates that M cannot distinguish a correct response from a random one. On the other hand, M doesn’t actually need to know whether the response on the left is correct or not in order to perform a successful mauling attack. Imagine, for example, the MIM who mauls R’s challenge to the left execution and mauls C’s response back. Such an M will prevent E from extracting \tilde{m} because M only correctly answers E’s query if given a correct response to its own left query, which E cannot give. Of course we will prove that no M with such behavior can exist, but this proof is highly non-trivial.

Another question which our extractor raises is “how can E tell a correct response from an incorrect one?” As we have described it, the hiding of Com ensures that it cannot. However, a small modification to the E described above fixes this. Instead of asking for one new share, E rewinds twice to the beginning of the right query phase and asks for two different new shares.

The key observation is that if M answers both queries correctly then the three shares it holds (the two it received plus the one it got as input) are collinear, whereas if M answers at least one incorrectly they are overwhelmingly likely to NOT be collinear. This is the first appearance of a tangeable payoff of the algebraicity of our protocol. For example, the protocol of [Goy11] (which is similar to ours, but strictly combinatorial in nature) does not have this algebraic verification technique at its disposal and must introduce use extra rounds into the protocol to ensure its extractor can reconstruct \tilde{m} .

E is given as input a transcript of a complete commit phase in both the left and right interactions. We denote the transcript with the letter \mathbb{T} . Specifically,

$$\mathbb{T} = (\mathbf{Com}, \tilde{\mathbf{Com}}, \alpha, \tilde{\alpha}, \mathbf{a}, \tilde{\mathbf{a}}, \pi, \tilde{\pi}).$$

Since E will not be interested in the proofs $(\pi, \tilde{\pi})$, and since M is deterministic (and so $\mathbf{Com}, \alpha, \tilde{a}$ are uniquely determined by $\mathbf{Com}, \tilde{\alpha}$, and \mathbf{a}) we will often just write $\mathbb{T} = (\mathbf{Com}, \tilde{\alpha}, \mathbf{a})$.

Definition 3 (Accepting Transcript). *We say that $\mathbb{T} \in \text{ACC}$ if both π and $\tilde{\pi}$ are accepting proofs.*

The soundness of the ZK ensures that if $\mathbb{T} \in \text{ACC}$ then query vectors $\tilde{\alpha}$ and α are answered correctly. We say that M aborts if M behaves in such a way as to make $\mathbb{T} \notin \text{ACC}$. Note this includes the case when M acts in an obviously corrupt fashion, causing C or R to abort.

The extractor E gets $\mathbb{T} \in \text{ACC}$ as input so the probabilities which arise in our analysis often are conditioned on the event $\mathbb{T} \in \text{ACC}$. We denote this with the convenient shorthand $\Pr_{\mathbb{T} \in \text{ACC}}(\dots)$ instead of $\Pr_{\mathbb{T}}(\dots | \mathbb{T} \in \text{ACC})$. For fixed \mathbf{Com} , M can be thought of as a deterministic map, mapping right query vectors to left ones. We write $\alpha = M(\tilde{\alpha})$ to be consistent with this point of view. We assume that the transcript E gets as input is consistent with exactly one right commitment \tilde{m} . As $\langle C, R \rangle$ is statistically binding, this happens with overwhelming probability.

See Figure 3 below for a formal description of the extractor. Note that there are two ways for E to fail to output \tilde{m} . The first is if E fails to extract any value and outputs **FAIL**. The other is if E accidentally extracts an incorrect value $\tilde{m}' \neq \tilde{m}$.

Tags: Let $\{t_i\}_i$ and $\{\tilde{t}_i\}_i$ be the left and right tags, respectively, in error corrected form.

Input: $\mathbb{T} = (\mathbf{Com}, \tilde{\alpha}, \mathbf{a}) \in \text{ACC}$, and a large value $N = \text{poly}(\lambda)$. E is given oracle access to M .

Extraction procedure: For $j \in [N]$:

1. Rewind M to the beginning of step 2 of the protocol:

- generate a random right challenge vector $\tilde{\beta}_j = (\tilde{\beta}_{1,j}, \dots, \tilde{\beta}_{n,j})$, where $\tilde{\beta}_{i,j} \in [2^{\tilde{t}_i}]$.
- Feed M with $\tilde{\beta}_j$ and receive challenge $\beta_j = (\beta_{1,j}, \dots, \beta_{n,j})$ for left interaction.

2. Feed $\mathbf{b}_j = (b_{1,j}, \dots, b_{n,j})$ to M where $b_{i,j} = \begin{cases} a_i, & \beta_{i,j} = \alpha_i \\ r \xleftarrow{R} \mathbb{Z}_q, & \beta_{i,j} \neq \alpha_i \end{cases}$. Get $\tilde{\mathbf{b}}_j = (\tilde{b}_{1,j}, \dots, \tilde{b}_{n,j})$.

3. For each $i \in [n]$ use $\{(\tilde{\alpha}_i, \tilde{a}_i), (\tilde{\beta}_{i,j}, \tilde{b}_{i,j})\}$ to interpolate a line and recover candidate $\tilde{m}_{i,j}$.

4. Repeat steps 1-3. Let $\tilde{\gamma}_j = (\tilde{\gamma}_{1,j}, \dots, \tilde{\gamma}_{n,j})$ be new right challenge vector and $\tilde{\mathbf{c}}_j = (\tilde{c}_{1,j}, \dots, \tilde{c}_{n,j})$ be corresponding response. Let $(\tilde{m}'_{1,j}, \dots, \tilde{m}'_{n,j})$ be recovered candidates.

5. If for some $i \in [n]$, $\tilde{m}_{i,j} = \tilde{m}'_{i,j}$ and $\{(\tilde{\alpha}_i, \tilde{a}_i), (\tilde{\beta}_{i,j}, \tilde{b}_{i,j}), (\tilde{\gamma}_{i,j}, \tilde{c}_{i,j})\}$ are collinear output $\tilde{m}_{i,j}$ and halt.

Output: Output **FAIL**.

Figure 3: The Extractor E .

Theorem 2 (Sufficient for Theorem 1). *Let E be the extractor described in Figure 3, and let \mathbb{T} be the transcript it is given as input. Let \tilde{m} be M 's commitment in the right interaction of \mathbb{T} . Then*

$$\Pr_{\mathbb{T} \in \text{ACC}}(E(\mathbb{T}) \neq \tilde{m}) \leq p,$$

where the probability is over $\mathbb{T} \in \text{ACC}$ and the randomness of E .

4.2 Extractable, Useful and Troublesome Transcripts

We now begin to chip away at Theorem 2 by examining special classes of transcripts on which a mauling attack will fail. This allows us to gather properties which the remaining pertinent transcripts must satisfy which will aid our future analysis. In this section we focus on the commitment message of the protocol.

Recall the two ways E can fail: by outputting **FAIL** or by outputting incorrect $\tilde{m}' \neq \tilde{m}$. Note that the second way requires M to answer a pair of queries incorrectly but in such a way so that they yield the same candidate message and they pass the collinearity test. In this case we say that M answers *incorrectly but collinearly*.

Definition 4 (Incorrect but Collinear). *Fix a main thread transcript $\mathbb{T} = (\mathbf{Com}, \tilde{\alpha}, a)$ and an $i \in \{1, \dots, n\}$. Let $(\tilde{\beta}, \tilde{b})$ and $(\tilde{\gamma}, \tilde{c})$ denote two query/response pairs arising during the execution of E while rewinding M . Suppose that interpolating $(\tilde{\beta}_i, \tilde{b}_i)$ and $(\tilde{\gamma}_i, \tilde{c}_i)$ against the main thread's point $(\tilde{\alpha}_i, \tilde{a}_i)$ produces the same candidate message \tilde{m}' . We say that M answers $(\tilde{\beta}_i, \tilde{\gamma}_i)$ incorrectly but collinearly if:*

1. $\tilde{m}' \neq \tilde{m}$; and
2. $\{(\tilde{\alpha}_i, \tilde{a}_i), (\tilde{\beta}_i, \tilde{b}_i), (\tilde{\gamma}_i, \tilde{c}_i)\}$ are collinear.

We define the set $\text{IBC}^i(\mathbf{Com}, \tilde{\alpha}_i) = \{(\tilde{\beta}, \tilde{\gamma}) : M \text{ answers } (\tilde{\beta}_i, \tilde{\gamma}_i) \text{ incorrectly but collinearly}\}$. Finally, define

$$\text{IBC}(\tilde{\beta}, \tilde{\gamma}) = \{\mathbb{T} \in \text{ACC} : (\tilde{\beta}, \tilde{\gamma}) \in \text{IBC}^i(\mathbf{Com}, \tilde{\alpha}_i) \text{ for some } i\}.$$

Note that $\text{IBC}^i(\mathbf{Com}, \tilde{\alpha}_i)$ is well defined given \mathbb{T} and E 's randomness. Intuitively IBC is the set of transcripts for which E might fail because M answers incorrectly but collinearly. The following claim shows that these transcripts rarely occur.

Claim 1. *For any $(\tilde{\beta}, \tilde{\gamma})$, $\Pr_{\mathbb{T} \in \text{ACC}}(\mathbb{T} \in \text{IBC}(\tilde{\beta}, \tilde{\gamma})) = \text{negl}(\lambda)$.*

Proof. Fix $i \in \{1, \dots, n\}$ and let $\mathbb{T}, \mathbb{T}' \in \text{ACC}$ be main threads with the same prefix **Com** but different i -th right queries $\tilde{\alpha}_i$ and $\tilde{\alpha}'_i$. Moreover, fix E 's randomness arbitrarily making it deterministic, so that the sets $\text{IBC}^i(\tilde{\alpha}_i)$ and $\text{IBC}^i(\tilde{\alpha}'_i)$ are defined. Note that $\text{IBC}^i(\tilde{\alpha}_i)$ and $\text{IBC}^i(\tilde{\alpha}'_i)$ are disjoint. Indeed, suppose $(\tilde{\beta}, \tilde{\gamma}) \in \text{IBC}^i(\tilde{\alpha}_i) \cap \text{IBC}^i(\tilde{\alpha}'_i)$. Then the four points

$$\{(\tilde{\alpha}_i, \tilde{a}_i), (\tilde{\alpha}'_i, \tilde{a}'_i), (\tilde{\beta}_i, \tilde{b}_i), (\tilde{\gamma}_i, \tilde{c}_i)\}$$

are collinear. This means that the line they all lie on is correct because $(\tilde{\alpha}_i, \tilde{a}_i)$ and $(\tilde{\alpha}'_i, \tilde{a}'_i)$ are correct ($\mathbb{T}, \mathbb{T}' \in \text{ACC}$) and so $(\tilde{\beta}, \tilde{\gamma}) \notin \text{IBC}^i(\tilde{\alpha}_i) \cup \text{IBC}^i(\tilde{\alpha}'_i)$ as M answered $\tilde{\beta}_i$ and $\tilde{\gamma}_i$ correctly. Therefore, for a fixed prefix **Com** and extractor queries $(\tilde{\beta}, \tilde{\gamma})$, there is at most one value of $\tilde{\alpha}_i$ such that $(\tilde{\beta}, \tilde{\gamma}) \in \text{IBC}^i(\tilde{\alpha}_i)$. As the set of possible $\tilde{\alpha}_i$ is superpolynomial, the chances that R 's query $\tilde{\alpha}$ in \mathbb{T} is such that $(\tilde{\beta}, \tilde{\gamma}) \in \bigcup_i \text{IBC}^i(\tilde{\alpha}_i)$ for any extractor query $(\tilde{\beta}, \tilde{\gamma})$ is negligible. The result follows. \square

As our extractor only asks polynomially many pairs of new queries $(\tilde{\beta}, \tilde{\gamma})$, we see that E outputs the wrong message $\tilde{m}' \neq \tilde{m}$ with negligible probability. This means that if E fails, it does so because it does not receive correct answers to its queries. We define **EXT**, the set of “extractable” transcripts, on which M has a non-negligible chance of answering a query correctly even given that its queries are answered by E .

Definition 5 (Extractable Transcripts). Fix $\varepsilon^* = (\lambda/N)^{1/2}$. We define

$$\text{EXT}_i = \{(\mathbf{Com}, \tilde{\alpha}) : \Pr_{\tilde{\beta}}(M \text{ correctly answers } \tilde{\beta}_i | \mathbf{Com} \text{ \& } M's \text{ queries answered by } E) \geq \varepsilon^*\}.$$

Set $\text{EXT} = \{\mathbb{T} \in \text{ACC} : (\mathbf{Com}, \tilde{\alpha}) \in \text{EXT}_i \text{ for some } i\}$.

Intuitively, **EXT** is the set of transcripts such that M has good probability of providing at least one pair of correct answers to a pair of queries asked in a rewind despite the fact that E provides random answers to M 's queries. We now prove that if a transcript is in **EXT** then E succeeds in extracting \tilde{m} whp.

Claim 2. $\Pr_{\mathbb{T}}(E(\mathbb{T}) = \mathbf{FAIL} | \mathbb{T} \in \text{EXT}) = \text{negl}(\lambda)$, where the probability is over \mathbb{T} and the randomness of E .

Proof. Let \mathbf{E}_j be the event that there exists an i such that M answers both i -th queries correctly in rewind j . Since $\mathbb{T} \in \text{EXT}$ we have that $\Pr(\mathbf{E}_j) \geq (\varepsilon^*)^2 = \lambda/N$ for all j . As the \mathbf{E}_j are independent,

$$\Pr_{\mathbb{T}}(E(\mathbb{T}) = \mathbf{FAIL} | \mathbb{T} \in \text{EXT}) = \Pr(\text{not } \mathbf{E}_j \ \forall j | \mathbb{T} \in \text{EXT}) \leq \left(1 - \frac{\lambda}{N}\right)^N = \text{negl}(\lambda).$$

□

Having looked at transcripts on which E succeeds whp, we next examine a set of transcripts on which E trivially fails. These are transcripts which M was lucky to complete given the commitment phase. Indeed, if every time E rewinds M simply aborts, E will have no chance of extracting \tilde{m} .

Definition 6 (Useful Transcripts). Fix non-negligible $\delta < \frac{1}{3}$ and (temporarily) define

$$W = \{\mathbf{Com} : \Pr_{\mathbb{T}}(\mathbb{T} \in \text{ACC} | \mathbf{Com}) \leq \delta p^2\}.$$

Set $\text{USEFUL} := \{\mathbb{T} \in \text{ACC} : \mathbf{Com} \notin W\}$.

Informally, W is the set of partial transcripts for which M is unlikely to complete the protocol, so **USEFUL** is the set of transcripts such that if M is rewound and executed again on a different query, the protocol will complete successfully with good probability. We note that most transcripts are indeed useful.

Claim 3. $\Pr_{\mathbb{T} \in \text{ACC}}(\mathbb{T} \notin \text{USEFUL}) \leq \delta p$.

Proof. We have

$$\Pr_{\mathbb{T} \in \text{ACC}}(\mathbf{Com} \in W) = \Pr_{\mathbb{T}}(\mathbf{Com} \in W | \mathbb{T} \in \text{ACC}) \leq \frac{\Pr_{\mathbb{T}}(\mathbb{T} \in \text{ACC} | \mathbf{Com} \in W)}{\Pr_{\mathbb{T}}(\mathbb{T} \in \text{ACC})} \leq \delta p,$$

using the definition of W and the fact that $\Pr_{\mathbb{T}}(\mathbb{T} \in \text{ACC}) \geq p$.

□

Transcripts in **EXT** are those for which M is likely to correctly answer a right query even given incorrect responses to its own left queries. On the other hand, **USEFUL** can be thought of as the transcripts for which M answers the right queries correctly if given correct answers to its left queries. This leads us to the following definition.

Definition 7 (Troublesome Transcripts). *We define $\text{TRB} = \text{USEFUL} \setminus \text{EXT}$.*

Transcripts in **TRB** are troublesome as essentially, they are transcripts for which M answers the right queries correctly if given correct answers to its left queries, but incorrectly if given incorrect answers to its left queries. Certainly, the hiding of Com ensures that M cannot *know* whether it receives correct or random responses to its queries on the left. So this difference in behavior suggests that we may be able to use M to break the hiding of Com . However, it is not so easy. Keep in mind, M does not have to know whether it is giving a correct or incorrect answer on the left. Indeed, almost all mauling attacks one could imagine have the property that M answers correctly on the right if and only if it gets correct answers on the left. The following lemma comprises the heart of our analysis.

Lemma 1. *If Com is computationally hiding then there exists a constant $\delta' < \frac{1}{3}$ such that*

$$\Pr_{\mathbb{T} \in \text{ACC}}(\mathbb{T} \in \text{TRB}) \leq \delta' p.$$

Lemma 1 combined with Claims 1 through 3 give us

$$\begin{aligned} \Pr_{\mathbb{T} \in \text{ACC}}(\mathbb{E}(\mathbb{T}) \neq \tilde{m}) &\leq \Pr_{\mathbb{T} \in \text{ACC}}(\mathbb{T} \notin \text{USEFUL}) + \Pr_{\mathbb{T} \in \text{ACC}}(\mathbb{T} \in \text{TRB}) \\ &+ \Pr_{\mathbb{T}}(\mathbb{E}(\mathbb{T}) = \mathbf{FAIL} | \mathbb{T} \in \text{EXT}) \\ &+ \Pr_{\mathbb{T} \in \text{ACC}}(\mathbb{T} \in \text{IBC}(\tilde{\beta}, \tilde{\gamma}) \text{ for some } (\tilde{\beta}, \tilde{\gamma}) \text{ asked by } \mathbb{E}) \\ &\leq \delta p + \delta' p + \mathbf{negl}(\lambda) < p, \end{aligned}$$

proving Theorem 2.

5 Proof of Lemma 1

5.1 Proof Overview

We prove Lemma 1 by defining the notion of “query dependence”, and then considering the possible different ways in which M ’s left queries α can depend on right queries $\tilde{\alpha}$. Intuitively, $\alpha_{i'}$ being dependent on $\tilde{\alpha}_i$ is the result of M performing a mauling attack. Suppose that M mauls $\text{Com}(f_{i'})$ in order to obtain $\text{Com}(\tilde{f}_i)$. Then M does not know \tilde{f}_i and so cannot hope to answer $\tilde{\alpha}_i$ except by mauling C ’s answer to $\alpha_{i'}$. Therefore, if M is rewound to the beginning of step 2 and asked a different query vector $\tilde{\beta}$ such that $\tilde{\beta}_i = \tilde{\alpha}_i$, M will have to ask β such that $\beta_{i'} = \alpha_{i'}$ if it wants to answer successfully. This is the idea of query dependence: if $\tilde{\alpha}_i$ is asked on the right, then $\alpha_{i'}$ must be asked on the left.

Recall that in the introduction we considered a copying MIM who attempts to maul C ’s commitment by simply copying and pasting messages between the left and right sessions. Such an attack is a very simple example of a mauling attack in which each α_i is dependent on $\tilde{\alpha}_i$. We saw this attack is foiled by the large number of left tags which differ from all right tags, preventing the right query $\tilde{\alpha}$ from being a legal left query except with negligible probability. In fact, we prove in Claim 7 that all mauling attacks in which each α_i depends on $\tilde{\alpha}_i$ will fail whp.

This encourages us to investigate what else can happen. We arrive at three possibilities.

- **UNBAL:** There exist $i' > i$ such that $\alpha_{i'}$ depends on $\tilde{\alpha}_i$.
- **1–2:** There exist (i_1, i_2, i') such that $\alpha_{i'}$ depends on both $\tilde{\alpha}_{i_1}$ and $\tilde{\alpha}_{i_2}$.
- **IND:** There exists i such that each $\alpha_{i'}$ does *not* depend on $\tilde{\alpha}_i$.

In the actual proof we formalize the above possibilities using precise conditional probability statements. We keep it informal here, however, in order to convey as much intuition as possible.

Note that if none of the above three events occur then α_i depends on $\tilde{\alpha}_i$ for all i which is what we hope happens. We complete the proof by showing that each of the three events cannot happen except with very small probability. However, this is easier said than done. Consider, for example, the mauling attack which results in 1–2. Intuitively, if $\alpha_{i'}$ is dependent on both $\tilde{\alpha}_{i_1}$ and $\tilde{\alpha}_{i_2}$ then M is using C’s response $f_{i'}(\alpha_{i'})$ on the left to produce both $\tilde{f}_{i_1}(\tilde{\alpha}_{i_1})$ and $\tilde{f}_{i_2}(\tilde{\alpha}_{i_2})$ on the right. On the one hand it is extremely unlikely that a single polynomial evaluation on the left contains enough information to allow M to correctly give two random evaluations on the right. On the other hand, this intuition alone isn’t enough to say that 1–2 can’t occur as the argument is information theoretic in nature. Indeed, any statement one wishes to make about M’s behavior in the query phase must have a computational proof as an unbounded M can query however it wants to and then simply break the hiding of the commitments in the first message to learn the \tilde{f}_i and answer correctly.

The key claim which allows us to capitalize on our information theoretic intuition is Claim 8 which states that if the left query α has a superpolynomial number of preimage right queries $\tilde{\alpha}$ then either E succeeds in extracting \tilde{m} or M can be used to break the hiding of $\langle C, R \rangle$. The proof is technical; at this point we give only some intuition which speaks to the truth of Claim 8. Full details can be found in Section 5.3. If there are superpolynomially many $\tilde{\alpha}$ such that $M(\tilde{\alpha}) = \alpha$, the chances that M can use C’s response by itself to answer $\tilde{\alpha}$ are negligible. It follows that either M must be content to not answer most of the $\tilde{\alpha}$ such that $M(\tilde{\alpha}) = \alpha$ (the probability of which can be bounded using a straightforward conditional probability argument) or M must know some “extra information” about the \tilde{f}_i which allows him to provide a correct response to $\tilde{\alpha}$. But this means that either M will use this extra information to correctly answer $\tilde{\alpha}$ even when given a random answer to α on the left (in which case E succeeds in extracting \tilde{m}), or M is choosing to utilize this extra information only when C answers correctly on the left. However, the hiding of the commitment in the first message ensures that M cannot *know* whether he receives correct responses on the left or not, and this difference in behavior will allow us to use M to break hiding.

Armed with Claim 8, we can now make definitive statements about **UNBAL** and **1–2**. For example, if **UNBAL** occurs then $\alpha_{i'}$ is dependent on $\tilde{\alpha}_i$ for some $i' > i$, and so if R asks a new right challenge with the same i –th query, M will fix $\alpha_{i'}$ on the left. However, as $i' > i$, $\alpha_{i'}$ is drawn from a much larger challenge space than $\tilde{\alpha}_i$, and so M is “wasting challenge space”. Specifically, the residual right challenge space with the i –th query fixed to $\tilde{\alpha}_i$ is superpolynomially larger than the residual left challenge space with $\alpha_{i'}$ fixed, and so with high probability, we will find ourselves in a situation where the left query has superpolynomially many right query preimages. By Claim 8, this must not happen except with negligible probability. This simple combinatorial argument is essentially the content of Claim 5. In Section 5.2 we prove Claims 5 through 7 which show that if either **UNBAL** or **1–2** or “not (**UNBAL** or **1–2** or **IND**)” occur, then the left query will have superpolynomially many right query preimages. The proofs of Claims 6 and 7 are more involved than that of Claim 5, but they are still purely combinatorial.

Finally, we prove in Claim 9 that IND cannot happen using another reduction to hiding. It uses the same framework as Claim 8 and has similar underlying intuition (again, we defer the technical discussion and formal proof to Section 5.3). Here the main point is that if IND occurs then there exists a right query $\tilde{\alpha}_i$ on which no $\alpha_{i'}$ on the left is dependent. Intuitively this means that M does not need any of the left challenges in order to correctly return $\tilde{f}_i(\tilde{\alpha}_i)$, implying that he knows some information about the polynomial \tilde{f}_i . As in the intuition for Claim 8 this means either that extraction is successful, or that M is breaking hiding.

5.2 Analyzing Dependencies

In Section 4.2, we looked at the commitment message of $\langle C, R \rangle$, and established that it suffices to consider only transcripts $\mathbb{T} \in \text{TRB}$ in order to prove Theorem 1. We now consider the query message of $\langle C, R \rangle$. Let R and L be the sets of right and left query vectors respectively. In this section we will often fix a commitment message \mathbf{Com} (implicitly fixing $\tilde{\mathbf{Com}} = M(\mathbf{Com})$) in which case M can be thought of as a deterministic function $M : R \rightarrow L$ mapping $\tilde{\alpha}$ to α . In the rest of this section we will frequently consider subsets of R and L . Whenever we do so, we assume that \mathbf{Com} is fixed (even if do not mention it explicitly). This is because we are really interested in how M behaves on these subsets, and M is not defined as a function until \mathbf{Com} is fixed.

Definition 8 (Honest Queries). *For fixed \mathbf{Com} , we say that a right query vector $\tilde{\alpha} \in R$ is honest if M answers $\tilde{\alpha}$ honestly in the right interaction given correct responses to its queries $\alpha = M(\tilde{\alpha})$ in the left interaction. We denote the set of honest right query vectors by $\text{HON}_{\mathbf{Com}}$, or just HON when \mathbf{Com} is clear from context.*

Let $R^i(\tilde{\alpha}_i)$ and $L^{i'}(\alpha_{i'})$ denote the sets of right and left query vectors whose i -th and i' -th coordinates are fixed on $\tilde{\alpha}_i$ and $\alpha_{i'}$, respectively. We write $M : R^i(\tilde{\alpha}_i) \rightarrow L^{i'}(\alpha_{i'})$ if M maps a τ -fraction of $R^i(\tilde{\alpha}_i)$ to $L^{i'}(\alpha_{i'})$. Similarly, define $\text{HON}^i(\tilde{\alpha}_i) := R^i(\tilde{\alpha}_i) \cap \text{HON}$. Finally, we write $\Pr_{\tilde{\alpha} \in \text{HON}}(\dots)$ as shorthand for $\Pr_{\tilde{\alpha}}(\dots | \tilde{\alpha} \in \text{HON})$.

Claim 4. *Let \mathbf{Com} be the prefix of a transcript $\mathbb{T} \in \text{USEFUL}$. Then*

1. $|\text{HON}| \geq \delta p^2 |R|$;
2. *for any $i \in [n]$, if we (temporarily) define $Z_\tau^i = \{\tilde{\alpha}_i \in [2^{\tilde{t}_i}] : |\text{HON}^i(\tilde{\alpha}_i)| \leq \tau |R^i(\tilde{\alpha}_i)|\}$, then*

$$\Pr_{\tilde{\alpha} \in \text{HON}}(\tilde{\alpha}_i \in Z_\tau^i) \leq \frac{\tau}{\delta p^2}.$$

Intuitively, 2 says that with good probability, for all values $\tilde{\alpha}_i$ which appear in an honest $\tilde{\alpha}$, $\text{HON}^i(\tilde{\alpha}_i)$ comprises at least a τ -fraction of $R^i(\tilde{\alpha}_i)$.

Proof. 1 follows immediately from the definition of USEFUL . For 2, we have

$$\Pr_{\tilde{\alpha} \in \text{HON}}(\tilde{\alpha}_i \in Z_\tau^i) \leq \frac{\Pr_{\tilde{\alpha}}(\tilde{\alpha} \in \text{HON} | \tilde{\alpha}_i \in Z_\tau^i)}{\Pr_{\tilde{\alpha}}(\tilde{\alpha} \in \text{HON})} \leq \frac{\tau}{\delta p^2}$$

□

Parameters. We have already introduced parameters $n = \mathcal{O}(\lambda)$, non-negligible $p = p(\lambda)$, constants $\delta, \delta' < 1/3$, and $\varepsilon^* = (\lambda/N)^{1/2}$ for $N = \text{poly}(\lambda)$, a yet unspecified polynomial. Shortly we will introduce the values $\varepsilon = 1/n - \varepsilon'$ where $\varepsilon' = 1/2n^2$. We will require that $\varepsilon^* \leq \sigma \delta^2 p^5/16$ and also that $\varepsilon^* \leq n \varepsilon' (\varepsilon' \delta \delta' p^3)^2/2048$, where $\sigma = \varepsilon' (\delta')^2 p^4/257n^3$ is defined for convenience. All in all, setting $N = \omega(\lambda n^{10} p^{-18})$ will suffice. We stress that there is no reason to believe that N must be such a large polynomial; it arises due to our analysis, which is not concerned with minimizing N . We now formally define ε -dependence.

Definition 9 (ε -dependence). For fixed $\mathbb{T} \in \text{ACC}$ and $i, i' \in \{1, \dots, n\}$, we say $\alpha_{i'}$ is ε -dependent on $\tilde{\alpha}_i$ if $\Pr_{\tilde{\beta} \in \text{HON}}(\beta_{i'} = \alpha_{i'} | \tilde{\beta}_i = \tilde{\alpha}_i) \geq \varepsilon$.

We stress that it is important to condition on the event $\tilde{\beta} \in \text{HON}$ because any statement about \mathbf{M} 's behavior during the query/response phase is useless unless \mathbf{M} actually plans to successfully complete the right protocol.

Note that if $\varepsilon > \varepsilon'$ and $\alpha_{i'}$ is ε -dependent on $\tilde{\alpha}_i$, then $\alpha_{i'}$ is automatically also ε' -dependent on $\tilde{\alpha}_i$. Additionally, notice that though our definition does leave open the possibility that there could be more than one value which is ε -dependent on $\tilde{\alpha}_i$, there can only be polynomially many (at most ε^{-1} to be exact). We call these values the ε -dependencies of $\tilde{\alpha}_i$. This notion is different from ε -dependence defined above only because the ε -dependencies exist regardless of what queries are asked in \mathbb{T} , whereas we only say that $\alpha_{i'}$ is ε -dependent on $\tilde{\alpha}_i$ if both $\tilde{\alpha}_i$ and $\alpha_{i'}$ appear in \mathbb{T} . For the remainder of the proof we fix non-negligible values ε and ε' such that $\varepsilon = 1/n - \varepsilon'$ and $\varepsilon' = 1/2n^2$.

Definition 10 (Special Sets of Transcripts). Fix (as a function of λ), $\omega = \omega(1)$. Define the following sets of transcripts:

1. $\text{UNBAL} := \{\mathbb{T} \in \text{ACC} : \exists i' > i \text{ st } \alpha_{i'} \text{ is } \varepsilon' \text{-dependent on } \tilde{\alpha}_i\};$
2. $1-2 := \{\mathbb{T} \in \text{ACC} : \exists (i_1, i_2, i') \text{ st } \alpha_{i'} \text{ is } \varepsilon' \text{-dependent on both } \tilde{\alpha}_{i_1} \text{ and } \tilde{\alpha}_{i_2}\};$
3. $\text{IND} := \{\mathbb{T} \in \text{ACC} : \exists i \text{ st } \Pr_{\tilde{\beta} \in \text{HON}}(\beta_{i'} \neq \alpha_{i'} \ \forall i' | \tilde{\beta}_i = \tilde{\alpha}_i) \geq \varepsilon' n\};$
4. $\text{SUPER-POLY} := \{\mathbb{T} \in \text{ACC} : \#\{\tilde{\alpha} \in \text{HON} : \mathbf{M}(\tilde{\alpha}) = \alpha\} \geq \lambda^\omega\}.$

Note that if $\mathbb{T} \notin \text{IND}$ then for all i , there exists an i' such that $\alpha_{i'}$ is ε -dependent on $\tilde{\alpha}_i$.

What follows is a sequence of claims which sheds light on the relationships between the special sets of transcripts defined above. The statements all resemble one another and their proofs are similar, and are in order of increasing complexity. We recommend those readers who are interested in understanding the proofs to read them in order as it will make the later ones much easier to understand. Readers who are interested in understanding the general flow of our overall proof will most likely find reading the proof of Claim 5 and the statements of Claims 6 and 7 more than sufficient.

Claim 5. Fix $\sigma = \frac{\varepsilon' (\delta')^2 p^4}{257n^3}$. If $\Pr_{\mathbb{T} \in \text{ACC}}(\mathbb{T} \in \text{TRB} \cap \text{UNBAL}) \geq \frac{\delta' p}{4}$, then

$$\Pr_{\mathbb{T} \in \text{ACC}}(\mathbb{T} \in \text{TRB} \cap \text{SUPER-POLY}) \geq \sigma.$$

Proof. We begin with the inequality $\Pr_{\mathbb{T}}(\mathbb{T} \in \text{TRB} \cap \text{UNBAL}) \geq \delta' p^2/4$ (using the fact that $\Pr_{\mathbb{T}}(\mathbb{T} \in \text{ACC}) \geq p$). Fix a random commit message **Com**. With probability at least $\delta' p^2/8$

over **Com**, we have that $\Pr_{\tilde{\alpha} \in \text{HON}}(\mathbb{T} \in \text{TRB} \cap \text{UNBAL} | \mathbf{Com}) \geq \delta' p^2 / 8$. Now let $i' > i$ be such that $\Pr_{\tilde{\alpha} \in \text{HON}}(\alpha_{i'} \text{ is } \varepsilon' \text{ -- dependent on } \tilde{\alpha}_i \text{ \& } \mathbb{T} \in \text{TRB} | \mathbf{Com}) \geq \delta' p^2 / 8n^2$. Such (i, i') must exist by definition of **UNBAL**. Temporarily define the sets X and Z as follows:

- $X = \{\tilde{\alpha} \in \text{HON} : \alpha_{i'} \text{ is } \varepsilon' \text{ -- dependent on } \tilde{\alpha}_i \text{ \& } \mathbb{T} \in \text{TRB}\};$
- $Z = \{\tilde{\alpha}_i \in [2^{\tilde{t}_i}] : |\text{HON}^i(\tilde{\alpha}_i)| \leq \tau |R^i(\tilde{\alpha}_i)|\}, \text{ where } \tau = \frac{\delta \delta' p^4}{16n^2}.$

Remark. Defining temporary sets X , Y and Z will be a recurring theme throughout the proofs in this section (though in this first proof we only need X and Z). X will be a set of queries which display evidence of a particular type of query dependence; and Y and Z will be sets of queries in a particular coordinate in the right session which display some certain bad behavior. We will lower bound the probability that $\tilde{\alpha} \in X$ using the claim's hypotheses, and we will upper bound the probability that $\tilde{\alpha}_i \in Z$ using Claim 4 (in fact, Z is the same set as Z_τ^i in the statement of Claim 4, just with the indices omitted for simplicity). Though it doesn't appear here, we will also upper bound the probability that $\tilde{\alpha}_i \in Y$ using simple conditional probability. We now proceed.

We have

$$\begin{aligned} \Pr_{\tilde{\alpha} \in \text{HON}}(\tilde{\alpha} \in X \text{ \& } \tilde{\alpha}_i \notin Z) &\geq \Pr_{\tilde{\alpha} \in \text{HON}}(\tilde{\alpha} \in X) - \Pr_{\tilde{\alpha} \in \text{HON}}(\tilde{\alpha}_i \in Z) \\ &\geq \frac{\delta' p^2}{8n^2} - \frac{\delta' p^2}{16n^2} = \frac{\delta' p^2}{16n^2}, \end{aligned}$$

using Claim 4. However, if $\tilde{\alpha} \in \text{HON}$ is such that $\tilde{\alpha} \in X \text{ \& } \tilde{\alpha}_i \notin Z$, then $\mathbb{T} \in \text{TRB}$ and M maps an ε' -- fraction of $\text{HON}^i(\tilde{\alpha}_i)$ into $L^{i'}(\alpha_{i'})$. Furthermore, as

$$|\text{HON}^i(\tilde{\alpha}_i)| \geq \tau |R^i(\tilde{\alpha}_i)| \geq \tau 2^{\omega(\log \lambda)} |L^{i'}(\alpha_{i'})|$$

(using $i' > i$ and that the tags are well spaced), we see that M , when restricted appropriately, is superpolynomially many to one on average. This means that $\mathbb{T} \in \text{TRB}$ and that α has superpolynomially many preimages in **HON** whp, and so

$$\Pr_{\mathbb{T} \in \text{ACC}}(\mathbb{T} \in \text{TRB} \cap \text{SUPER-POLY}) \geq \frac{\delta' p^2}{8} \cdot \frac{\delta' p^2}{16n^2} \cdot (1 - \text{negl}(\lambda)) = \frac{(\delta')^2 p^4}{128n^2} - \text{negl}(\lambda) > \sigma.$$

□

Claim 6. Fix $\sigma = \frac{\varepsilon'(\delta')^2 p^4}{257n^3}$. If $\Pr_{\mathbb{T} \in \text{ACC}}(\mathbb{T} \in \text{TRB} \cap 1-2) \geq \frac{\delta' p}{4}$, then

$$\Pr_{\mathbb{T} \in \text{ACC}}(\mathbb{T} \in \text{TRB} \cap \text{SUPER-POLY}) \geq \sigma.$$

Proof. Fix a commitment message **Com**. With probability at least $\delta' p^2 / 8$ over the choice of **Com**, we have $\Pr_{\tilde{\alpha} \in \text{HON}}(\mathbb{T} \in \text{TRB} \cap 1-2 | \mathbf{Com}) \geq \delta' p^2 / 8$. Let (i_1, i_2, i') be such that

$$\Pr_{\tilde{\alpha} \in \text{HON}}(\alpha_{i'} \text{ is } \varepsilon' \text{ -- dependent on } \tilde{\alpha}_{i_1} \text{ and } \tilde{\alpha}_{i_2} \text{ \& } \mathbb{T} \in \text{TRB} | \mathbf{Com}) \geq \frac{\delta' p^2}{8n^3}.$$

Such (i_1, i_2, i') must exist by definition of 1-2. Temporarily define sets X , Y and Z :

- $X = \{\tilde{\alpha} \in \text{HON} : \alpha_{i'} \text{ is } \varepsilon' \text{ -- dependent on both } \tilde{\alpha}_{i_1} \text{ and } \tilde{\alpha}_{i_2} \text{ \& } \mathbb{T} \in \text{TRB}\};$
- $Y = \{\tilde{\alpha}_{i_1} \in [2^{\tilde{t}_{i_1}}] : \Pr_{\tilde{\alpha} \in \text{HON}}(\alpha \in X | (\mathbf{Com}, \tilde{\alpha}_{i_1})) \leq \frac{\varepsilon' \delta' p^2}{16n^3}\};$

- $Z = \{\tilde{\alpha}_{i_1} \in [2^{t_{i_1}}] : |\text{HON}^{i_1}(\tilde{\alpha}_{i_1})| \leq \tau |R^{i_1}(\tilde{\alpha}_{i_1})|\}$, where $\tau = \frac{\varepsilon' \delta' p^4}{32n^3}$.

Note that with **Com** fixed as above we have

$$\Pr_{\tilde{\alpha} \in \text{HON}}(\tilde{\alpha} \in X) \geq \frac{\delta' p^2}{8n^3}; \Pr_{\tilde{\alpha}}(\tilde{\alpha}_{i_1} \in Y | \tilde{\alpha} \in X) \leq \frac{\varepsilon'}{2}; \text{ and } \Pr_{\tilde{\alpha} \in \text{HON}}(\tilde{\alpha}_{i_1} \in Z) \leq \frac{\varepsilon' \delta' p^2}{32n^3}.$$

Now, for $v \in [2^{t_{i'}}]$, let \mathbf{E}_v be the event “ $\alpha_{i'} = v$.” Note that if $\Pr_{\tilde{\alpha}}(\mathbf{E}_v | \tilde{\alpha} \in X) > 0$ then v is an ε' –dependency of $\tilde{\alpha}_{i_1}$. Let $D^{i'}(\tilde{\alpha}_{i_1}) \subset [2^{t_{i'}}]$ be the set of all ε' –dependencies of $\tilde{\alpha}_{i_1}$. Then for fixed $\tilde{\alpha}_{i_1}$, we define a probability mass function on $D^{i'}(\tilde{\alpha}_{i_1})$ by $P(v) = \Pr_{\tilde{\alpha}}(\mathbf{E}_v | \tilde{\alpha} \in X \ \& \ \tilde{\alpha}_{i_1})$. We say that $v^* \in D^{i'}(\tilde{\alpha}_{i_1})$ is *maximal* if $P(v^*) \geq P(v)$ for all $v \in D^{i'}(\tilde{\alpha}_{i_1})$. Clearly for a random $\tilde{\alpha} \in X$, the resulting $\alpha_{i'}$ is maximal with probability at least ε' as $|D^{i'}(\tilde{\alpha}_{i_1})| \leq (\varepsilon')^{-1}$. We now lower bound the quantity $V = \Pr_{\tilde{\alpha} \in \text{HON}}(\tilde{\alpha} \in X \ \& \ \tilde{\alpha}_{i_1} \notin Y \cup Z \ \& \ \alpha_{i'} \text{ maximal})$. We have

$$\begin{aligned} V &\geq \Pr_{\tilde{\alpha} \in \text{HON}}(\tilde{\alpha} \in X \ \& \ \tilde{\alpha}_{i_1} \notin Y \ \& \ \alpha_{i'} \text{ maximal}) - \Pr_{\tilde{\alpha} \in \text{HON}}(\tilde{\alpha}_{i_1} \in Z) \\ &\geq \Pr_{\tilde{\alpha} \in \text{HON}}(\tilde{\alpha} \in X) \cdot \left[\Pr_{\tilde{\alpha}}(\tilde{\alpha}_{i_1} \notin Y \ \& \ \alpha_{i'} \text{ maximal} | \tilde{\alpha} \in X) \right] - \frac{\varepsilon' \delta' p^2}{32n^3} \\ &\geq \frac{\delta' p^2}{8n^3} \cdot \left[\Pr_{\tilde{\alpha}}(\alpha_{i'} \text{ maximal} | \tilde{\alpha} \in X) - \Pr_{\tilde{\alpha}}(\tilde{\alpha}_{i_1} \in Y | \tilde{\alpha} \in X) \right] - \frac{\varepsilon' \delta' p^2}{32n^3} \\ &\geq \frac{\delta' p^2}{8n^3} \cdot \frac{\varepsilon'}{2} - \frac{\varepsilon' \delta' p^2}{32n^3} = \frac{\varepsilon' \delta' p^2}{32n^3}. \end{aligned}$$

Finally we show that if $\tilde{\alpha}$ is such that “ $\tilde{\alpha} \in X \ \& \ \tilde{\alpha}_{i_1} \notin Y \cup Z \ \& \ \alpha_{i'}$ is maximal”, then $\mathbb{T} \in \text{TRB}$ (where \mathbb{T} is the transcript resulting from $\tilde{\alpha}$) and with probability at least $\tau' = \delta(\delta')^2(\varepsilon')^4 p^6 / 512n^6$ over $\tilde{\beta} \in \text{HON}$, we will have $\beta_{i'} = \alpha_{i'}$. This completes the proof of Claim 6 as it means that \mathbf{M} maps a τ' –fraction of **HON** into $L^{i'}(\alpha_{i'})$ and since

$$|\text{HON}| \geq \delta p^2 |R| \geq \delta p^2 2^{\omega(\log \lambda)} |L^{i'}(\alpha_{i'})|$$

(using the “well spaced” property of the tags), \mathbf{M} is superpolynomially many to one on average when restricted appropriately. Just like in the proof of Claim 5, this gives

$$\Pr_{\mathbb{T} \in \text{ACC}}(\mathbb{T} \in \text{TRB} \cap \text{SUPER-POLY}) \geq \frac{\delta' p^2}{8} \cdot \frac{\varepsilon' \delta' p^2}{32n^3} - \text{negl}(\lambda) > \sigma.$$

So all that remains is to prove that if $\tilde{\alpha}$ is such that “ $\tilde{\alpha} \in X \ \& \ \tilde{\alpha}_{i_1} \notin Y \cup Z \ \& \ \alpha_{i'}$ is maximal” then $\Pr_{\tilde{\beta} \in \text{HON}}(\beta_{i'} = \alpha_{i'}) \geq \tau'$. The maximality of $\alpha_{i'}$ combined with the fact that $\tilde{\alpha}_{i_1} \notin Y$ ensure that if $\tilde{\gamma} \in \text{HON}^{i_1}(\tilde{\alpha}_{i_1})$ is chosen at random, then with probability at least $(\varepsilon')^2 \delta' p^2 / 16n^3$ over $\tilde{\gamma}$ we will have “ $\gamma_{i'}$ is ε' –dependent on $\tilde{\gamma}_{i_1}$ and $\tilde{\gamma}_{i_2} \ \& \ \gamma_{i'} = \alpha_{i'}$ ”. Moreover, as $\tilde{\alpha}_{i_1} \notin Z$, a random $\tilde{\gamma} \in R^{i_1}(\tilde{\alpha}_{i_1})$ will be such that “ $\gamma_{i'}$ is ε' –dependent on $\tilde{\gamma}_{i_1}$ and $\tilde{\gamma}_{i_2} \ \& \ \gamma_{i'} = \alpha_{i'}$ ” with probability at least $\delta(\delta')^2(\varepsilon')^3 p^6 / 512n^6 = \tau' / \varepsilon'$.

So choose a random $\tilde{\gamma} \in R^{i_1}(\tilde{\alpha}_{i_1})$ and then choose a random $\tilde{\beta} \in \text{HON}^{i_2}(\tilde{\gamma}_{i_2})$. Clearly such a $\tilde{\beta}$ is a random element of **HON**. As “ $\gamma_{i'}$ is ε' –dependent on $\tilde{\gamma}_{i_2} \ \& \ \gamma_{i'} = \alpha_{i'}$ ” with probability at least τ' / ε' , the definition of ε' –dependence ensures that $\beta_{i'} = \gamma_{i'} = \alpha_{i'}$ with probability at least τ' , as desired. \square

Claim 7. Fix $\sigma = \frac{\varepsilon'(\delta')^2 p^4}{257n^3}$. If $\Pr_{\mathbb{T} \in \text{ACC}}(\mathbb{T} \in \text{TRB} \setminus (\text{UNBAL} \cup 1-2 \cup \text{IND})) \geq \frac{\delta' p}{4}$, then

$$\Pr_{\mathbb{T} \in \text{ACC}}(\mathbb{T} \in \text{TRB} \cap \text{SUPER-POLY}) \geq \sigma.$$

Proof. Fix a commitment message **Com**. With probability at least $\delta'p^2/8$ over the choice of **Com**, we have $\Pr_{\tilde{\alpha} \in \text{HON}}(\mathbb{T} \in \text{TRB} \setminus (\text{UNBAL} \cup 1-2 \cup \text{IND}) | \mathbf{Com}) \geq \delta'p^2/8$. Now consider the consequences of $\mathbb{T} \notin (\text{UNBAL} \cup 1-2 \cup \text{IND})$:

- if $\mathbb{T} \notin \text{UNBAL}$, then for all $i' > i$, $\alpha_{i'}$ cannot be ε -dependent on $\tilde{\alpha}_i$ (since $\varepsilon \geq \varepsilon'$);
- if $\mathbb{T} \notin 1-2$, then there do not exist (i_1, i_2, i') such that $\alpha_{i'}$ is ε -dependent on $\tilde{\alpha}_{i_1}$ and $\tilde{\alpha}_{i_2}$;
- if $\mathbb{T} \notin \text{IND}$ then for every i , there exists at least one i' such that $\alpha_{i'}$ is ε -dependent on $\tilde{\alpha}_i$.

It follows that if $\mathbb{T} \notin (\text{UNBAL} \cup 1-2 \cup \text{IND})$ then for each i , α_i must be ε -dependent on $\tilde{\alpha}_i$. Indeed, α_1 must be ε -dependent on $\tilde{\alpha}_1$ as something must depend on $\tilde{\alpha}_1$ and it cannot be $\alpha_{i'}$ for $i' > 1$. Next, either α_1 or α_2 must be ε -dependent on $\tilde{\alpha}_2$ and it cannot be α_1 as that is already dependent on $\tilde{\alpha}_1$. Continuing in this fashion, we deduce that each α_i is ε -dependent on $\tilde{\alpha}_i$.

Now, going one step further in examining the consequences of $\mathbb{T} \notin (\text{UNBAL} \cup 1-2 \cup \text{IND})$, since each α_i is ε -dependent on $\tilde{\alpha}_i$ and $\mathbb{T} \notin 1-2$, it must be that $\alpha_{i'}$ is not ε' -dependent on $\tilde{\alpha}_i$ for all $i' \neq i$. It follows that for all i , $\Pr_{\tilde{\beta} \in \text{HON}}(\exists i' \neq i \text{ st } \beta_{i'} = \alpha_{i'} | \tilde{\beta}_i = \tilde{\alpha}_i) \leq \varepsilon'n$. As $\mathbb{T} \notin \text{IND}$, we have that for all i ,

$$\begin{aligned} \Pr_{\tilde{\beta} \in \text{HON}}(\beta_i = \alpha_i | \tilde{\beta}_i = \tilde{\alpha}_i) &\geq \Pr_{\tilde{\beta} \in \text{HON}}(\exists i' \text{ st } \beta_{i'} = \alpha_{i'} | \tilde{\beta}_i = \tilde{\alpha}_i) \\ &\quad - \Pr_{\tilde{\beta} \in \text{HON}}(\exists i' \neq i \text{ st } \beta_{i'} = \alpha_{i'} | \tilde{\beta}_i = \tilde{\alpha}_i). \\ &\geq 1 - \varepsilon'n - \varepsilon'n = 1 - 2\varepsilon'n, \end{aligned}$$

so we see that, in fact, each α_i is $(1 - 2\varepsilon'n)$ -dependent on $\tilde{\alpha}_i$. As $2\varepsilon'n < \frac{1}{2}$, each $\tilde{\alpha}_i$ has a unique $(1 - 2\varepsilon'n)$ -dependence.

Now, choose a random $\tilde{\alpha} \in \text{HON}$ and let $S = \{i \in [n] : \tilde{t}_i \leq t_i\}$, $\tilde{\alpha}_S = (\tilde{\alpha}_i)_{i \in S}$ and define $\text{HON}^S(\tilde{\alpha}_S) = \bigcap_{i \in S} \text{HON}^i(\tilde{\alpha}_i)$. Define $R^S(\tilde{\alpha}_S)$ and $L^S(\alpha_S)$ similarly. Now, temporarily define sets X, Y, Z as follows:

- $X = \{\tilde{\alpha} \in \text{HON} : \alpha_i \text{ is } (1 - 2\varepsilon'n) \text{ - dependent on } \tilde{\alpha}_i \ \forall i \ \& \ \mathbb{T} \in \text{TRB}\};$
- $Y = \{\tilde{\alpha}_S : \Pr_{\tilde{\alpha} \in \text{HON}}(\tilde{\alpha} \in X | \tilde{\alpha}_S) \leq \frac{\delta'p^2}{16}\};$
- $Z = \{\tilde{\alpha}_S : |\text{HON}^S(\tilde{\alpha}_S)| \leq \tau |R^S(\tilde{\alpha}_S)|\}, \text{ where } \tau = \frac{\delta\delta'p^4}{32}.$

Note that

$$\Pr_{\tilde{\alpha} \in \text{HON}}(\tilde{\alpha} \in X) \geq \frac{\delta'p^2}{8}; \Pr_{\tilde{\alpha}}(\tilde{\alpha}_S \in Y | \tilde{\alpha} \in X) \leq \frac{1}{2}; \text{ and } \Pr_{\tilde{\alpha} \in \text{HON}}(\tilde{\alpha}_S \in Z) \leq \frac{\delta'p^2}{32},$$

and so $\Pr_{\tilde{\alpha} \in \text{HON}}(\tilde{\alpha} \in X \ \& \ \tilde{\alpha}_S \notin Y \cup Z) \geq \delta'p^2/32$. Now suppose that some $\tilde{\alpha} \in \text{HON}$ is such that “ $\tilde{\alpha} \in X \ \& \ \tilde{\alpha}_S \notin Y \cup Z$ ”. Then $\mathbb{T} \in \text{TRB}$ and for a randomly selected $\tilde{\beta} \in \text{HON}^S(\tilde{\alpha}_S)$, $\tilde{\beta} \in X$ with probability at least $\delta'p^2/16$. But if $\tilde{\alpha}, \tilde{\beta} \in X$ and $\tilde{\alpha}_S = \tilde{\beta}_S$, then $\alpha_S = \beta_S$. Indeed, all $\tilde{\alpha}_i$ have a unique $(1 - 2\varepsilon'n)$ -dependency, meaning that if α_i and β_i are dependent on $\tilde{\alpha}_i$ and $\tilde{\beta}_i$ and $\tilde{\alpha}_i = \tilde{\beta}_i$ for all $i \in S$, then it must be that $\alpha_i = \beta_i$ for all $i \in S$.

It follows that if “ $\tilde{\alpha} \in X \ \& \ \tilde{\alpha}_S \notin Y \cup Z$ ” then $\mathbb{T} \in \text{TRB}$ and \mathbf{M} maps a τ' -fraction of $\text{HON}^S(\tilde{\alpha}_S)$ into $L^S(\alpha_S)$ where $\tau' = \delta'p^2/16$. Moreover,

$$|\text{HON}^S(\tilde{\alpha}_S)| \geq \tau |R^S(\tilde{\alpha}_S)| \geq \tau 2^{\omega(\log \lambda)} |L^S(\alpha_S)|$$

(using the “good distance and balance” property of the tags). As in the proofs of Claims 5 and 6, we have

$$\Pr_{\mathbb{T} \in \text{ACC}}(\mathbb{T} \in \text{TRB} \cap \text{SUPER-POLY}) \geq \frac{\delta' p^2}{8} \cdot \frac{\delta' p^2}{32} - \text{negl}(\lambda) > \sigma.$$

□

5.3 Reductions to the Hiding of $\langle C, R \rangle$

In this section we complete the proof of Lemma 1 by proving two claims which show how to use an M with unlikely behavior to break the hiding of $\langle C, R \rangle$. We first give an intuitive description of our method of argument. This description is slightly technical but does not get into the specifics of either Claim 8 or Claim 9.

We construct an adversary \mathcal{A} who takes part in the hiding game for $\langle C, R \rangle$. \mathcal{A} is defined as follows:

- \mathcal{A} chooses random $m_0, m_1 \in \mathbb{Z}_q$ and sends (m_0, m_1) to a challenger \mathcal{C} , signaling the beginning of the hiding game of $\langle C, R \rangle$.
- \mathcal{A} instantiates M and runs two sessions of $\langle C, R \rangle$ until the end of the commit phase of both executions, forwarding the messages it receives as C to \mathcal{C} . In the left execution, \mathcal{C} commits to m_u for secret $u \in \{0, 1\}$. More specifically:
 - \mathcal{A} , acting as R , sends $\tilde{\sigma}$ to M , and receives σ which it forwards to \mathcal{C} .
 - \mathcal{A} then receives **Com** from \mathcal{C} which it forwards to M , and receives **Com**.
 - \mathcal{A} sends random $\tilde{\alpha}$ such that $\tilde{\alpha}_i \in [2^{\tilde{t}_i}]$ to M , receiving α which it forwards to \mathcal{C} .
 - \mathcal{A} receives **a** from \mathcal{C} which it forwards to M , obtaining \tilde{a} .
 - \mathcal{A} continues forwarding messages between M and \mathcal{C} during the zero-knowledge proof phase of $\langle C, R \rangle$, playing honestly as R in the right interaction.
 - When the proofs are finished, \mathcal{A} verifies both π and $\tilde{\pi}$. If either is not accepted, \mathcal{A} aborts. Let $\mathbb{T} = (\mathbf{Com}, \tilde{\alpha}, \mathbf{a})$ be the resulting transcript.
- \mathcal{A} chooses random $u' \in \{0, 1\}$ and defines polynomial vector \mathbf{f} such that $\mathbf{f}(\alpha) = \mathbf{a}$ and every coordinate of \mathbf{f} has constant term $m_{u'}$.
- \mathcal{A} rewinds M to the beginning of the query phase of the right execution and sends a new query $\tilde{\beta}$, receiving left query β . It can do this many times, resulting in a set of new right queries $\{\tilde{\beta}, \tilde{\gamma}, \dots\}$.
- \mathcal{A} answers the left queries it obtained in the previous step with \mathbf{f} , and receives a right response. It collects the points it receives on the right into the set $\{(\tilde{\alpha}, \tilde{a}), (\tilde{\beta}, \tilde{b}), (\tilde{\gamma}, \tilde{c}), \dots\}$.
- \mathcal{A} tests whether the points $\{(\tilde{\alpha}, \tilde{a}), (\tilde{\beta}, \tilde{b}), (\tilde{\gamma}, \tilde{c}), \dots\}$ satisfy some condition. If so, then \mathcal{A} outputs u' , if not it outputs $1 - u'$.

Exactly what condition \mathcal{A} tests for will change between the two proofs. In the proof of Claim 8, \mathcal{A} checks that the points $\{(\tilde{\alpha}, \tilde{a}), (\tilde{\beta}, \tilde{b}), (\tilde{\gamma}, \tilde{c})\}$ are collinear, while in the proof of Claim 9, \mathcal{A} checks that $\tilde{b}_i = \tilde{a}_i$ for some preselected i . The important thing however, is that the condition be satisfied when M answers correctly, but not when M answers incorrectly. Note that if $u' = u$ then responses

generated with \mathbf{f} are correct and so if $\mathbb{T} \in \text{USEFUL}$, then we can lower bound the probability that \mathbf{M} answers correctly on the right using Claim 4. On the other hand, if $u' \neq u$ then the responses on the left are random. If $\mathbb{T} \notin \text{EXT}$ then we have an upper bound on the probability that \mathbf{M} answers any right query correctly. These observations together tell us that there is a non-negligible gap between the probability that the condition is satisfied when $u' = u$ and when $u' \neq u$. This gap translates to \mathcal{A} having a noticeable advantage in winning the hiding game.

There are two main issues with the above outline which need to be addressed. We discuss them informally here in order to exhibit the difficulties faced when trying to push the above intuition through. The first is that we have assumed that $\mathbb{T} \in \text{TRB}$ when in reality we are only allowed to assume that $\mathbb{T} \in \text{TRB}$ with probability at least $\frac{\delta' p}{4}$. Fact 1 below says essentially that if the gap between the condition being satisfied when $u' = u$ and not when $u' \neq u$ is large enough, this does not matter.

A second, more subtle, issue is that we can only use $\mathbb{T} \notin \text{EXT}$ to upper bound the probability that \mathbf{M} answers correctly on the right when $u' \neq u$ if the answers on the left are distributed as if they were answered by the extractor, \mathbf{E} . Recall that \mathbf{E} is instructed to answer randomly on the left unless the left query is the same as in the main thread, in which case \mathbf{E} reuses the main thread's answer. Note that this process is exactly the same as answering one query according to \mathbf{f} when $u' \neq u$. However, if \mathbf{M} is rewound more than once and asks left challenges $\{\beta, \gamma\}$, the responses it receives will no longer be random. Indeed, $\{(\alpha, \mathbf{a}), (\beta, \mathbf{b}), (\gamma, \mathbf{c})\}$ will be collinear so certainly not random (and hence, not distributed as \mathbf{E} 's responses). This will mean, for example, that we will not be able to use Claim 1 to argue that \mathbf{M} 's responses on the right cannot be incorrect but collinear. In fact, if \mathbf{M} receives random but collinear responses on the left, it might well be the case that \mathbf{M} 's right responses are incorrect but collinear (consider for example the copying MIM). Instead, we will have to use the additional hypothesis that $\mathbb{T} \in \text{SUPER-POLY}$ along with the observation that β is answered identically to how \mathbf{E} would answer it to bound the probability that $\{(\tilde{\alpha}, \tilde{\mathbf{a}}), (\tilde{\beta}, \tilde{\mathbf{b}}), (\tilde{\gamma}, \tilde{\mathbf{c}})\}$ are collinear when $u' \neq u$. For details see Claim 8 below.

In the proof of Claim 9, \mathcal{A} rewinds \mathbf{M} and asks a new challenge $\tilde{\beta}$ such that $\tilde{\beta}_i = \tilde{\alpha}_i$ for some i . Note that if β is such that $\beta_{i'} = \alpha_{i'}$ for some i' , then \mathbf{M} will receive at least one correct answer on the left regardless of whether $u' = u$ or not. If $u' \neq u$, this will mean that the answers \mathbf{M} receives on the left are not distributed identically to the answers \mathbf{M} would receive from \mathbf{E} . Indeed, suppose that some $\alpha_{i'}$ is dependent on $\tilde{\alpha}_i$. Then if $\tilde{\beta}$ such that $\tilde{\beta}_i = \tilde{\alpha}_i$ is asked on the right by \mathcal{A} , \mathbf{M} will ask β on the left with $\beta_{i'} = \alpha_{i'}$, and get at least one correct response. If, on the other hand, $\tilde{\beta}$ is asked on the right by \mathbf{E} , then with overwhelming probability, $\tilde{\beta}$ does not share any query with the query vector asked in the main thread as \mathbf{E} draws its queries randomly, independent of \mathbb{T} . This means that $\beta_{i'}$ will likely not equal $\alpha_{i'}$, and so \mathbf{M} will get a random response instead of a correct one. This inherent difference between \mathcal{A} and \mathbf{E} means that we cannot use Claim 2 to upper bound the probability that \mathbf{M} answers correctly on the right. Instead we have to use the additional assumption that $\mathbb{T} \notin \text{IND}$ to ensure that β is completely distinct from α *even though* $\tilde{\beta}_i = \tilde{\alpha}_i$ on the right. Even with this assumption, the proof requires some delicacy to ensure that in fact the answers \mathcal{A} gives to \mathbf{M} are the same as the ones \mathbf{E} would give. For details see the proof of Claim 9.

Fact 1. *Consider an efficiently testable condition that the set $\{(\tilde{\alpha}, \tilde{\mathbf{a}}), (\tilde{\beta}, \tilde{\mathbf{b}}), (\tilde{\gamma}, \tilde{\mathbf{c}}), \dots\}$ either satisfies or not, as described in the above paragraphs. Let \mathbf{E} be an event such that:*

- $\Pr_{\mathbb{T} \in \text{ACC}}(\mathbf{E}) \geq \xi$;
- $\Pr(\text{Condition satisfied} | u' = u \ \& \ \mathbf{E}) \geq \xi'$;

- $\Pr(\text{Condition satisfied} | u' \neq u \ \& \ \mathbf{E}) \leq \xi''$,

for non-negligible values ξ, ξ', ξ'' satisfying $\xi'' \leq (p\xi\xi')/8$. Then there exists a PPT algorithm \mathcal{A} that breaks the hiding of $\langle C, R \rangle$.

Proof. Fix $\ell = 1/2\xi''$ and let \mathcal{A} play in an ℓ -way version of the usual hiding game of $\langle C, R \rangle$ as follows:

- \mathcal{A} chooses random $m_1, \dots, m_\ell \in \mathbb{Z}_q$ and sends (m_1, \dots, m_ℓ) to \mathcal{C} .
- \mathcal{A} instantiates M and runs two sessions of $\langle C, R \rangle$ until the end of the commit phase of both executions, forwarding the messages it receives as C to \mathcal{C} . In the left execution, \mathcal{C} commits to $m_{j'}$ for secret $j' \in [\ell]$.
- For each $j \in [\ell]$, \mathcal{A} defines polynomial vectors \mathbf{g}_j such that $\mathbf{g}_j(\alpha) = \mathbf{a}$ and every coordinate of \mathbf{g}_j has constant term m_j .
- \mathcal{A} rewinds M to the beginning of the query phase of the right execution and sends new queries $\tilde{\beta}, \tilde{\gamma}, \dots$, receiving left queries β, γ, \dots .
- For each $j \in [\ell]$, \mathcal{A} answers the left queries it obtained in the previous step with \mathbf{g}_j , and receives a right response. It collects the set $\{(\tilde{\alpha}, \tilde{\mathbf{a}}), (\tilde{\beta}, \tilde{\mathbf{b}}_j), (\tilde{\gamma}, \tilde{\mathbf{c}}_j), \dots\}_{j \in [\ell]}$.
- For each $j \in [\ell]$, \mathcal{A} tests whether the points $\{(\tilde{\alpha}, \tilde{\mathbf{a}}), (\tilde{\beta}, \tilde{\mathbf{b}}_j), (\tilde{\gamma}, \tilde{\mathbf{c}}_j), \dots\}$ satisfy the condition. If so, then \mathcal{A} outputs $j^* = j$ and halts.

Note that

$$\begin{aligned} \Pr(j^* = j') &\geq \Pr_{\mathbb{T}}(\mathbb{T} \in \text{ACC}) \cdot \Pr_{\mathbb{T} \in \text{ACC}}(\mathbf{E}) \\ &\quad \cdot \Pr(\text{Condition satisfied when } j = j' | \mathbf{E}) \\ &\quad \cdot \Pr(\text{Condition not satisfied whenever } j \neq j' | \mathbf{E}) \\ &\geq (p\xi\xi') \cdot \Pr(\text{Not } \mathbf{E}'_j \text{ for all } j \neq j' | \mathbf{E}). \end{aligned}$$

where \mathbf{E}'_j is the event

\mathbf{E}'_j : “Conditions are satisfied when \mathbf{g}_j is used to answer left queries.”

We are given that $\Pr(\mathbf{E}'_j | \mathbf{E}) \leq \xi''$ for all $j \neq j'$, and as the \mathbf{E}'_j are independent this means that the expected number of \mathbf{E}'_j which occur is at most $\xi''\ell = 1/2$. It follows that

$$\Pr(j^* = j') \geq (p\xi\xi') \cdot \Pr(\text{No } \mathbf{E}'_j \text{ occur when } j \neq j' | \mathbf{E}) \geq \frac{p\xi\xi'}{2} \geq \frac{2}{\ell},$$

which means that \mathcal{A} 's chances of winning the hiding game are noticeably greater than $1/\ell$, violating the hiding of $\langle C, R \rangle$. \square

Claim 8. Fix $\sigma = \frac{\varepsilon'(\delta')^2 p^4}{257n^3}$. If $\Pr_{\mathbb{T} \in \text{ACC}}(\mathbb{T} \in \text{TRB} \cap \text{SUPER-POLY}) \geq \sigma$ then there exists a PPT algorithm \mathcal{A} who breaks the hiding of $\langle C, R \rangle$.

Proof. Our \mathcal{A} proceeds as follows.

- \mathcal{A} chooses random $m_0, m_1 \in \mathbb{Z}_q$ and begins the hiding game, sending (m_0, m_1) to \mathcal{C} . Then \mathcal{A} instantiates M and runs two sessions of $\langle C, R \rangle$ forwarding the messages it receives as C to \mathcal{C} . In the left interaction, \mathcal{C} commits to m_u for unknown $u \in \{0, 1\}$. Let $\mathbb{T} = (\mathbf{Com}, \tilde{\alpha}, \mathbf{a})$ be the resulting transcript. Additionally, \mathcal{A} chooses random $u' \in \{0, 1\}$ and defines the polynomial vector \mathbf{f} , to be the unique such vector so that $\mathbf{f}(\alpha) = \mathbf{a}$ and so that every coordinate of \mathbf{f} has constant term $m_{u'}$.
- \mathcal{A} chooses two new random challenge vectors $\tilde{\beta}$ and $\tilde{\gamma}$ such that each $\tilde{\beta}_i, \tilde{\gamma}_i \in [2^{t_i}]$. It rewinds M back to the beginning of the right execution's query message and sends $\tilde{\beta}$, receiving left query β . It responds with $\mathbf{b} = \mathbf{f}(\beta)$ and receives right response $\tilde{\mathbf{b}}$. It repeats this process, sending challenge $\tilde{\gamma}$, answering γ with $\mathbf{c} = \mathbf{f}(\gamma)$ and receiving $\tilde{\mathbf{c}}$.
- \mathcal{A} checks whether the points $\{(\tilde{\alpha}, \tilde{\mathbf{a}}), (\tilde{\beta}, \tilde{\mathbf{b}}), (\tilde{\gamma}, \tilde{\mathbf{c}})\}$ are collinear (by checking for collinearity in each coordinate). If so, \mathcal{A} outputs u' , if not \mathcal{A} outputs $1 - u'$.

In light of Fact 1, it suffices to construct an event \mathbf{E} such that:

1. $\Pr_{\mathbb{T} \in \text{ACC}}(\mathbf{E}) \geq \sigma$;
2. $\Pr(\{(\tilde{\alpha}, \tilde{\mathbf{a}}), (\tilde{\beta}, \tilde{\mathbf{b}}), (\tilde{\gamma}, \tilde{\mathbf{c}})\} \text{ collinear} | u' = u \ \& \ \mathbf{E}) \geq \delta^2 p^4$;
3. $\Pr(\{(\tilde{\alpha}, \tilde{\mathbf{a}}), (\tilde{\beta}, \tilde{\mathbf{b}}), (\tilde{\gamma}, \tilde{\mathbf{c}})\} \text{ collinear} | u' \neq u \ \& \ \mathbf{E}) \leq 2\varepsilon^*$,

since $\varepsilon^* \leq \sigma \delta^2 p^5 / 16$. Let \mathbf{E} (temporarily) be the event " $\mathbb{T} \in \text{TRB} \cap \text{SUPER-POLY}$." By hypothesis of Claim 8, $\Pr_{\mathbb{T} \in \text{ACC}}(\mathbf{E}) \geq \sigma$. Also, if $\mathbb{T} \in \text{USEFUL}$ and $u' = u$ then Claim 4 ensures that M answers $\tilde{\beta}$ and $\tilde{\gamma}$ correctly on the right with probability at least $(\delta p^2)^2$, which means that the probability that $\{(\tilde{\alpha}, \tilde{\mathbf{a}}), (\tilde{\beta}, \tilde{\mathbf{b}}), (\tilde{\gamma}, \tilde{\mathbf{c}})\}$ are collinear given $u' = u \ \& \ \mathbf{E}$ is at least as high. On the other hand,

$$\begin{aligned} \Pr(\{(\tilde{\alpha}, \tilde{\mathbf{a}}), (\tilde{\beta}, \tilde{\mathbf{b}}), (\tilde{\gamma}, \tilde{\mathbf{c}})\} \text{ collinear} | u' \neq u \ \& \ \mathbf{E}) &\leq \Pr(\text{collinear} | \tilde{\mathbf{b}} \text{ incorrect}) \\ &\quad + \Pr(\tilde{\mathbf{b}} \text{ correct} | u' \neq u \ \& \ \mathbf{E}) \\ &\leq \Pr(\text{collinear} | \tilde{\mathbf{b}} \text{ incorrect}) + \varepsilon^*, \end{aligned}$$

as if $u' \neq u$ then the answer M receives to β is distributed identically to the answer it would have received from E , and $\mathbb{T} \notin \text{EXT}$. Therefore, it suffices to show that

$$\Pr(\{(\tilde{\alpha}, \tilde{\mathbf{a}}), (\tilde{\beta}, \tilde{\mathbf{b}}), (\tilde{\gamma}, \tilde{\mathbf{c}})\} \text{ collinear} | \tilde{\mathbf{b}} \text{ incorrect}) = \text{negl}(\lambda).$$

Suppose that $\tilde{\alpha}, \tilde{\alpha}' \in \text{HON}$ are such that $M(\tilde{\alpha}) = \alpha = M(\tilde{\alpha}')$. Note that it cannot be the case that $\{(\tilde{\alpha}, \tilde{\mathbf{a}}), (\tilde{\beta}, \tilde{\mathbf{b}}), (\tilde{\gamma}, \tilde{\mathbf{c}})\}$ and $\{(\tilde{\alpha}', \tilde{\mathbf{a}}'), (\tilde{\beta}, \tilde{\mathbf{b}}), (\tilde{\gamma}, \tilde{\mathbf{c}})\}$ are collinear as this would mean that the four points

$$\{(\tilde{\alpha}, \tilde{\mathbf{a}}), (\tilde{\alpha}', \tilde{\mathbf{a}}'), (\tilde{\beta}, \tilde{\mathbf{b}}), (\tilde{\gamma}, \tilde{\mathbf{c}})\}$$

lie on the same line, and moreover, that this is the correct line as it contains the correct points $(\tilde{\alpha}, \tilde{\mathbf{a}})$ and $(\tilde{\alpha}', \tilde{\mathbf{a}}')$. This contradicts the hypothesis that $\tilde{\mathbf{b}}$ is an incorrect answer. So we see that there exists at most one $\tilde{\alpha} \in \text{HON}$ such that

1. $M(\tilde{\alpha}) = \alpha$;
2. $\{(\tilde{\alpha}, \tilde{\mathbf{a}}), (\tilde{\beta}, \tilde{\mathbf{b}}), (\tilde{\gamma}, \tilde{\mathbf{c}})\}$ are collinear.

As $\mathbb{T} \in \text{SUPER-POLY}$, there are at least λ^ω values of $\tilde{\alpha} \in \text{HON}$ such that number 1 holds, so the probability that \mathcal{A} chose the unique $\tilde{\alpha}$ such that both 1 and 2 hold is negligible. \square

Claim 9. If $\Pr_{\mathbb{T} \in \text{ACC}}(\mathbb{T} \in \text{TRB} \cap \text{IND}) \geq \frac{\delta'p}{4}$ then there exists a PPT algorithm \mathcal{A} who breaks the hiding of $\langle \mathbf{C}, \mathbf{R} \rangle$.

Proof. For each $i' \in [n]$, define the set

$$\text{FIXED}^{i'} = \{\mathbf{Com} : \exists v \in [2^{t_{i'}}] \text{ st } \Pr_{\tilde{\alpha} \in \text{HON}}(\alpha_{i'} = v | \mathbf{Com}) \geq \varepsilon\},$$

and let $\text{FIXED} = \{\mathbb{T} \in \text{ACC} : \mathbf{Com} \in \text{FIXED}^{i'} \text{ for some } i' \in [n]\}$.

Fact 2. Fix $\sigma = \frac{\varepsilon'(\delta')^2 p^4}{257n^3}$. If $\Pr_{\mathbb{T} \in \text{ACC}}(\mathbb{T} \in \text{TRB} \cap \text{FIXED}) \geq \frac{\delta'p}{8}$, then

$$\Pr_{\mathbb{T} \in \text{ACC}}(\mathbb{T} \in \text{TRB} \cap \text{SUPER-POLY}) \geq \sigma.$$

Proof of Fact 2. This proof is similar to (and easier than) the proofs of Claims 5 through 7. Fix commitment message \mathbf{Com} . Just as in the previous proofs, with probability at least $\delta'p^2/16$ over \mathbf{Com} , $\Pr_{\tilde{\alpha} \in \text{HON}}(\mathbb{T} \in \text{TRB} \cap \text{FIXED} | \mathbf{Com}) \geq \delta'p^2/16$. Let $i' \in [n]$ and $v \in [2^{t_{i'}}]$ be such that

$$\Pr_{\tilde{\alpha} \in \text{HON}}(\alpha_{i'} = v \ \& \ \mathbb{T} \in \text{TRB} | \mathbf{Com}) \geq \frac{\varepsilon \delta' p^2}{16n}.$$

Such (i', v) must exist by definition of FIXED . But this means that $\mathbb{T} \in \text{TRB}$ and \mathbf{M} maps at least a τ -fraction of HON into $L^{i'}(v)$, where $\tau = \varepsilon \delta' p^2 / 16n$. As

$$|\text{HON}| \geq \delta p^2 |R| \geq \delta p^2 2^{\omega(\log \lambda)} |L^{i'}(v)|,$$

(using the “well spaced” property of the tags), we see that \mathbf{M} , when restricted appropriately, is superpolynomially many to one on average. It follows that

$$\Pr_{\mathbb{T} \in \text{ACC}}(\mathbb{T} \in \text{TRB} \cap \text{SUPER-POLY}) \geq \frac{\delta'p^2}{16} \cdot \frac{\varepsilon \delta' p^2}{16n} - \text{negl}(\lambda) > \sigma.$$

□

In light of Fact 2 and Claim 8, it suffices to show that if $\Pr_{\tilde{\alpha} \in \text{HON}}(\mathbb{T} \in \text{TRB} \cap \text{IND} \setminus \text{FIXED}) \geq \delta'p/8$ then there exists a PPT \mathcal{A} who breaks the hiding of $\langle \mathbf{C}, \mathbf{R} \rangle$. Therefore, assume that this probability is at least $\delta'p/8$ and define \mathcal{A} as follows.

- \mathcal{A} chooses random $m_0, m_1 \in \mathbb{Z}_q$ and begins the hiding game, sending (m_0, m_1) to \mathcal{C} . Then \mathcal{A} instantiates \mathbf{M} and runs two sessions of $\langle \mathbf{C}, \mathbf{R} \rangle$ forwarding the messages it receives as \mathbf{C} to \mathcal{C} . In the left interaction, \mathcal{C} commits to m_u for unknown $u \in \{0, 1\}$. Let $\mathbb{T} = (\mathbf{Com}, \tilde{\alpha}, \mathbf{a})$ be the resulting transcript. Additionally, \mathcal{A} chooses random $u' \in \{0, 1\}$ and defines the polynomial vector \mathbf{f} , to be the unique such vector so that $\mathbf{f}(\alpha) = \mathbf{a}$ and so that every coordinate of \mathbf{f} has constant term $m_{u'}$.
- \mathcal{A} chooses random $i \in [n]$ and random legal challenge vector $\tilde{\beta}$ such that $\tilde{\beta}_i = \tilde{\alpha}_i$. It rewinds \mathbf{M} back to the beginning of the right execution’s query message and sends $\tilde{\beta}$, receiving left query β . If $\beta_{i'} = \alpha_{i'}$ for any $i' \in [n]$ then \mathcal{A} aborts. If not, \mathcal{A} responds with $\mathbf{b} = \mathbf{f}(\beta)$ receiving right response $\tilde{\mathbf{b}}$.
- \mathcal{A} checks whether $\tilde{b}_i = \tilde{a}_i$. If so, \mathcal{A} outputs u' , if not \mathcal{A} outputs $1 - u'$.

Just as in the proof of Claim 8, it suffices (by Fact 1) to construct an event \mathbf{E} such that:

1. $\Pr_{\mathbb{T} \in \text{ACC}}(\mathbf{E}) \geq \frac{\varepsilon' \delta' p}{16};$
2. $\Pr(\tilde{b}_i = \tilde{a}_i | u' = u \ \& \ \mathbf{E}) \geq \frac{\varepsilon' \delta \delta' p^3}{16};$
3. $\Pr(\tilde{b}_i = \tilde{a}_i | u' \neq u \ \& \ \mathbf{E}) \leq \frac{\varepsilon^*}{n \varepsilon' \delta p^2},$

since $\varepsilon^* \leq n \varepsilon' (\varepsilon' \delta \delta' p^3)^2 / 2048$. Temporarily let $Z = \{\tilde{\alpha}_i \in [2^{\tilde{t}_i}] : |\text{HON}^i(\tilde{\alpha}_i)| \leq \tau |R^i(\tilde{\alpha}_i)|\}$, where i is the index chosen by \mathcal{A} and $\tau = \varepsilon' \delta \delta' p^3 / 16$. Define the event

$$\mathbf{E} : \text{"}\mathbb{T} \in \text{TRB} \cap \text{IND} \setminus \text{FIXED} \ \& \ \mathcal{A} \text{ does not abort} \ \& \ \tilde{\alpha}_i \notin Z\text{"}$$

Note that

$$\begin{aligned} \Pr_{\mathbb{T} \in \text{ACC}}(\mathbf{E}) &\geq \Pr_{\mathbb{T} \in \text{ACC}}(\mathbb{T} \in \text{TRB} \cap \text{IND} \setminus \text{FIXED} \ \& \ \mathcal{A} \text{ not abort}) - \Pr_{\mathbb{T} \in \text{ACC}}(\tilde{\alpha} \in Z) \\ &\geq -\frac{\varepsilon' \delta' p}{16} + \Pr_{\mathbb{T} \in \text{ACC}}(\mathbb{T} \in \text{TRB} \cap \text{IND} \setminus \text{FIXED}) \cdot \\ &\quad \cdot \Pr_{\tilde{\alpha} \in \text{HON}}(\mathcal{A} \text{ not abort} | \mathbb{T} \in \text{TRB} \cap \text{IND} \setminus \text{FIXED}) \\ &\geq \frac{\delta' p}{8} \cdot \frac{1}{n} \cdot \varepsilon' n - \frac{\varepsilon' \delta' p}{16} = \frac{\varepsilon' \delta' p}{16}, \end{aligned}$$

by definition of **IND** (the $1/n$ appears because \mathcal{A} must guess the right value of $i \in [n]$). Moreover, as $\tilde{\alpha}_i \notin Z$, if $u' = u$ then \mathbf{M} answers $\tilde{\beta}$ and correctly on the right with probability at least $\varepsilon' \delta \delta' p^3 / 16$, which means that the probability that $\tilde{b}_i = \tilde{a}_i$ given $u' = u \ \& \ \mathbf{E}$ is at least as high.

Finally, we bound $\Pr(\tilde{b}_i = \tilde{a}_i | u' \neq u \ \& \ \mathbf{E})$. It does not quite work to try to use Claim 2 directly to argue that \mathbf{M} does not answer $\tilde{\beta}_i$ correctly if $u' \neq u$. This is because the answers \mathbf{M} receives if $u' \neq u$ are randomly distributed (this is ensured by \mathcal{A} aborting in case $\beta_{i'} = \alpha_{i'}$ for any i'), whereas the answers \mathbf{M} receives to β from \mathbf{E} are random only in the case that β differs in every coordinate from the α asked in the main thread. For this reason, we must also use the fact that $\mathbb{T} \notin \text{FIXED}$.

Consider now the interaction between \mathbf{M} and \mathbf{E} where the main thread \mathbf{E} receives as input has **Com** as the commitment message but has unspecified query and response messages. By definition, if **Com** $\notin \text{FIXED}^{i'}$ for all i' (ensuring that the main thread \mathbf{E} receives is not in **FIXED**), then for any $\gamma_{i'} \in [2^{t_{i'}}]$, $\Pr_{\tilde{\beta} \in \text{HON}}(\beta_{i'} = \gamma_{i'}) \leq \varepsilon$. It follows by the union bound that no matter what main thread left query γ occurs (we use γ so as not to be confused with the α that was asked by \mathbf{M} during its interaction with \mathcal{A} above),

$$\Pr_{\tilde{\beta}}(\beta_{i'} \neq \gamma_{i'} \ \forall \ i') \geq (1 - n\varepsilon) \cdot \Pr_{\tilde{\beta}}(\tilde{\beta} \in \text{HON}) \geq n\varepsilon' \delta p^2$$

(assuming also that **Com** is such that the transcript is in **USEFUL**). So we see that if the transcript \mathbf{E} receives as input is in $\text{TRB} \setminus \text{FIXED}$, then a good portion of the left queries which \mathbf{M} asks during its interaction with \mathbf{E} will not share any coordinate with the main thread query, and so \mathbf{M} will be given truly random responses. If in addition, the transcript given to \mathbf{E} is not in **EXT** then

$$\begin{aligned} \varepsilon^* &\geq \Pr_{\tilde{\beta}}(\mathbf{M} \text{ answers } \tilde{\beta}_i \text{ correctly} | \mathbf{E} \text{ answers } \beta) \\ &\geq \Pr_{\tilde{\beta}}(\mathbf{M} \text{ answers } \tilde{\beta}_i \text{ correctly} | \mathbf{E} \text{ answers } \beta \ \& \ \beta_{i'} \neq \gamma_{i'} \ \forall \ i') \cdot \Pr_{\tilde{\beta}}(\beta_{i'} \neq \gamma_{i'} \ \forall \ i') \\ &\geq (n\varepsilon' \delta p^2) \cdot \Pr_{\tilde{\beta}}(\mathbf{M} \text{ answers } \tilde{\beta}_i \text{ correctly} | \beta \text{ answered randomly}). \end{aligned}$$

And so we have

$$\begin{aligned} \Pr(\tilde{b}_i = \tilde{a}_i | u' \neq u \ \& \ \mathbf{E}) &= \Pr(\text{M answers } \tilde{\beta}_i \text{ corr.} | \beta \text{ answered rand.} \ \& \ \mathbb{T} \in \text{TRB} \setminus \text{FIXED}) \\ &\leq \frac{\varepsilon^*}{n\varepsilon'\delta p^2}, \end{aligned}$$

completing the proof of Claim 9. \square

Claims 5 through 9 combine to give that if Com is computationally hiding, then

$$\begin{aligned} \Pr_{\mathbb{T} \in \text{ACC}}(\mathbb{T} \in \text{TRB}) &\leq \Pr_{\mathbb{T} \in \text{ACC}}(\mathbb{T} \in \text{TRB} \cap \text{UNBAL}) + \Pr_{\mathbb{T} \in \text{ACC}}(\mathbb{T} \in \text{TRB} \cap 1-2) \\ &\quad + \Pr_{\mathbb{T} \in \text{ACC}}(\mathbb{T} \in \text{TRB} \cap \text{IND}) + \Pr_{\mathbb{T} \in \text{ACC}}(\mathbb{T} \in \text{TRB} \setminus (\text{UNBAL} \cup 1-2 \cup \text{IND})) \\ &\leq \frac{\delta'p}{4} + \frac{\delta'p}{4} + \frac{\delta'p}{4} + \frac{\delta'p}{4} = \delta'p, \end{aligned}$$

completing the proof of Lemma 1, Theorem 2 and Theorem 1.

6 Non-Malleability in 4-Rounds

In this section we show how to squeeze our non-malleable protocol $\langle C, R \rangle$ into 4 rounds. In the new protocol, the zero-knowledge messages are lifted up and sent together with the commit, challenge and response messages. We use a variant of the zero-knowledge argument of knowledge protocol of Feige and Shamir [FS90] in which V sets a trapdoor by proving a hard statement using a 3-round witness-hiding argument of knowledge (\mathcal{WHAOK}) and P uses a 3-round witness-indistinguishable argument of knowledge (\mathcal{WIAOK}) to prove either the original statement $x \in L$ or knowledge of V's trapdoor. If we instantiate the \mathcal{WIAOK} with the 3-round \mathcal{WIAOK} protocol of [FLS99] (where the statement to be proven can be chosen in the last round), then the protocol can be parallelized down to four rounds. We comment that there exist protocols for proving knowledge of commitment which are amenable to the Feige-Shamir parallelization technique without requiring a general \mathcal{NP} -reduction (such as Schnorr protocols based on DDH). Such protocols make a much better choice in practice.

We carefully parallelize the Feige-Shamir protocol with our 4-round basic component of $\langle C, R \rangle$ and obtain the first 4-round non-malleable commitment scheme. Our 4-round commitment scheme $\langle C, R \rangle_{\text{OPT}}$ appears in Figure 4. We slightly alter the \mathcal{WHAOK} used in the original Feige-Shamir construction (which assumes the existence of OWPs) in order to only rely on the existence of a OWF f . In the first round, R chooses $2n$ random pairs (x_i^b, y_i^b) for $i = 1, \dots, n$ and $b \in \{0, 1\}$ such that $y_i^b = f(x_i^b)$, and sends the y_i^b to C. Then C sends a random challenge $z \in \{0, 1\}^n$ and R returns $x_i^{z_i}$ for all i . C checks that indeed $y_i^{z_i} = f(x_i^{z_i})$ for all i (aborting if not) and uses a \mathcal{WIAOK} to prove either the original statement, or knowledge of some pair (x^0, x^1) such that $(y_i^0, y_i^1) = (f(x^0), f(x^1))$ for some i . It can be checked that the resulting 4-round protocol is still ZK. We let π denote the 3-round \mathcal{WIAOK} .

Proposition 2. *If OWFs exist then $\langle C, R \rangle_{\text{OPT}}$ is a 4-round statistically binding, non-malleable commitment scheme.*

Proof Sketch. Statistical binding follows immediately from the statistical binding property of Com. Computational hiding is shown similarly to Proposition 1.

Public Parameters: Tags t_1, \dots, t_n , prime q such that $q > 2^{t_i}$ for all i , and OWF $f : X \rightarrow Y$.

Committer's Private Input: Message $m \in \mathbb{F}_q$ to be committed to.

1. $R \rightarrow C$: Sample random $x_i^0, x_i^1 \in X$ for $i = 1, \dots, n$ and send $(y_i^0, y_i^1)_i = (f(x_i^0), f(x_i^1))_i$. Also send σ , the first message of Naor's commitment scheme.
2. $C \rightarrow R$: Send challenge $z \in \{0, 1\}^n$ along with the first message of π and the commitment vector $\mathbf{Com} = (\text{Com}_\sigma(m; s), \text{Com}_\sigma(r_1; s_1), \dots, \text{Com}_\sigma(r_n; s_n))$ as done in Step 1 of $\langle C, R \rangle$. The statement of π will be determined in step 4.
3. $R \rightarrow C$: Send $x_i^{z_i}$ for $i = 1, \dots, n$ along with challenge message of π and the challenge vector $\alpha = (\alpha_1, \dots, \alpha_n)$ as done in Step 2 of $\langle C, R \rangle$.
4. $C \rightarrow R$: Send the evaluation vector \mathbf{a} where $a_i = r_i \alpha_i + m$ as in Step 3 of $\langle C, R \rangle$ along with the last message of π proving the statement:
 - EITHER: $\exists ((m; s), (r_1; s_1), \dots, (r_n; s_n))$ such that:
 - $\mathbf{Com} = (\text{Com}_\sigma(m; s), \text{Com}_\sigma(r_1; s_1), \dots, \text{Com}_\sigma(r_n; s_n))$; and
 - $a_i = r_i \alpha_i + m$ for all i ;
 - OR: $\exists (x^0, x^1)$ such that $(y_i^0, y_i^1) = (f(x^0), f(x^1))$ for some i .

Figure 4: : 4-round non-malleable commitment scheme $\langle C, R \rangle_{\text{OPT}}$.

The proof that $\langle C, R \rangle_{\text{OPT}}$ is non-malleable against a synchronizing adversary follows exactly the same argument as the proof that $\langle C, R \rangle$ is non-malleable except that now when E is rewinding and answering M's queries randomly in the left interaction, it must complete π using M's trapdoor statement. This is not a problem; it just means that before E can start rewinding M back to the beginning of the right execution's query phase and trying to extract \tilde{m} , it must first rewind M back to the left execution's commit phase and extract M's trapdoor witness.

In order to prove non-malleability against a non-synchronizing M, we simply enumerate all of the other possibilities for M's scheduling and check that in all of them \tilde{m} can be extracted. As $\langle C, R \rangle_{\text{OPT}}$ has only four rounds, this is a very manageable task. It is easy to see that extraction is trivial from an M who uses any scheduling other than the synchronizing one. The key observations are: 1) an M who mauls must play the second message on the left before the second message on the right, 2) if the third and fourth messages on the right are consecutive then E can extract \tilde{m} from π . \square

Using our new commitment scheme $\langle C, R \rangle_{\text{OPT}}$, we obtain a simple 4-round non-malleable zero knowledge argument $\langle P, V \rangle$ for any language $L \in \mathcal{NP}$. A detailed description of $\langle P, V \rangle$ appears in Figure 5.

Proposition 3. *If OWFs exist then $\langle P, V \rangle$ is a 4-round non-malleable zero knowledge argument of knowledge for any $L \in \mathcal{NP}$.*

Proof Sketch. The proof of non-malleability is similar to the non-malleability of $\langle C, R \rangle_{\text{OPT}}$. The

Public Input: Tags t_1, \dots, t_n in error corrected form, large prime q and OWF $f : X \rightarrow Y$.

Common input: $x \in L$.

Input to the prover: A witness w for $x \in L$.

1. $V \rightarrow P$: Sample random $x_i^b \in X$ for $i = 1, \dots, n$ and $b \in \{0, 1\}$. Send $y_i^b = f(x_i^b)$ along with the first message of $\langle C(w), R \rangle$.
2. $P \rightarrow V$: Send challenge $z \in \{0, 1\}^n$ along with the second message of $\langle C(w), R \rangle$ and the first message of π for a statement to be proven later.
3. $V \rightarrow P$: Send $x_i^{z_i}$ for $i = 1, \dots, n$, the third message of $\langle C(w), R \rangle$ and the challenge message of π .
4. $P \rightarrow V$: Send the last message of $\langle C(w), R \rangle$ and the last message of π proving:
 - $x \in L$ and $\langle C(w), R \rangle$ was executed correctly; OR
 - $\exists (x^0, x^1)$ such that $(y_i^0, y_i^1) = (f(x^0), f(x^1))$ for some i .

Figure 5: The 4-round non malleable zero-knowledge argument of knowledge protocol $\langle P, V \rangle$.

zero-knowledge property follows by the ZK of [FS90] and the hiding of $\langle C, R \rangle_{\text{OPT}}$. Lastly, the AOK property can be derived by constructing an extractor that behaves as a honest verifier and extracts the witness by rewinding and sending different challenges. \square

Towards 3-round non-malleability. One natural question, in light of the above protocols, is “might we hope to obtain a 3-round NMC scheme assuming OWPs exist” (say by replacing Naor’s 2-round bit commitment scheme with Blum’s non-interactive one). However, this is unlikely as we need four rounds for the ZK argument which runs alongside the commit, query, response messages. Moreover, attempts to replace the ZK argument with some sort of 3-round WI run into the issue that E must extract M ’s trapdoor on the second round. So it seems that significantly new ideas are required in order to obtain 3-round NMC. In light of the 3-round lower bound of [Pas13] (using blackbox security reductions), 3-round NMC remains a fascinating open problem.
